MONTHLY BULLETIN
OF AGRICULTURAL INTELLIGENCE AND PLANT DISEASES

INDEX

Year 1921

ROME - PRINTING OFFICE OF THE INSTITUTE - 1923

THE INTERNATIONAL INSTITUTE OF AGRICULTURE

ORIGIN OF THE INSTITUTE AND SUMMARY OF THE INTERNATIONAL TREATY.

The International Institute of Agriculture was established under the International Treaty of 7 June 1905, which was ratified by forty governments. Twenty-two other governments have since adhered to the Institute.

It is a Government institution in which each country is represented by delegates. The Institute is composed of a General Assembly and a Permanent Committee.

The Institute, always confining its attention to the international aspect of the various questions concerned, shall:

(*a*) collect, study and publish as promptly as possible, statistical, technical, or economic information concerning farming, vegetable and animal products, trade in agricultural produce, and the prices prevailing in the various markets;

(*b*) communicate the above information as soon as possible to those interested;

(*c*) indicate the wages paid for farm work;

(*d*) record new diseases of plants which may appear in any part of the world, showing the regions infected, the progress of the diseases, and if possible, any effective remedies;

(*e*) study questions concerning agricultural co-operation, insurance and credit from every point of view; collect and publish information which might prove of value in the various countries for the organization of agricultural co-operation, insurance and credit;

(*f*) submit for the approval of the various governments, if necessary, measures for the protection of the common interests of farmers and for the improvement of their condition, utilizing for this purpose all available sources of information, such as resolutions passed by international or other agricultural congresses and societies, or by scientific and learned bodies, etc.

PERMANENT COMMITTEE
OF THE INTERNATIONAL INSTITUTE OF AGRICULTURE

President: His Exc. **Edoardo Pantano**, Senator, *Delegate of Italy.*
Vice-President: M. **Louis-Dop**, *Delegate of France.*
List of the Delegates to the Permanent Committee:

1	Argentina	I	Prof. Tomás Amadeo, Director-General, Ministry of Agricult.
2	Austria	IV	. . . .
3	Belgium	IV	O. Bolle.
4	Belgian Congo	V	O. Bolle.
5	Brazil	I	D. De Campos, Commercial Attaché to the Embassy.
6	Bulgaria	III	G. Radeff, Minister Plenipotentiary.
7	Chile	II	E. Villegas, Minister Plenipotentiary.
8	China	I	Tchou Yin, Secretary to the Legation.
9	Colombia	V	Prince Rufo Ruffo.
10	Costa-Rica	V	. . . .
11	Cuba	V	Dr. F. F. Falco.
12	Czechoslovakia	III	. . . .
13	Denmark	IV	H. de Kauffmann, Minister Plenipotentiary.
14	Ecuador	V	. . . .
15	Ethiopia	V	Prof. A. Mauri, Member of Italian Chamber of Deputies.
16	Egypt	II	Sir Thomas H. Elliott, Bart., K. C. B.
17	Finland	IV	H. G. Gummerus, Minister Plenipotentiary.
18	France	I	Louis-Dop, Vice-President of the Institute.
19	Algeria	III	Louis-Dop.
20	French West Africa	IV	Louis-Dop.
21	Indo-China	III	Louis-Dop.
22	Madagascar	V	Louis-Dop.
23	Morocco	III	Louis-Dop.
24	Tunis	IV	Louis-Dop.
25	Germany	I	Dr. Mehrens, Councillor of State.
26	Gr. Britain & Ireland	I	Sir Thomas H. Elliott, Bart., K. C. B.
27	Australia	III	Sir Thomas H. Elliott, Bart., K. C. B.
28	British India	II	Sir Thomas H. Elliott, Bart., K. C. B.
29	Canada	II	Sir Thomas H. Elliott, Bart., K. C. B.
30	New Zealand	IV	Sir Thomas H. Elliott, Bart., K. C. B.
31	Union of South Afr.	IV	Sir Thomas H. Elliott, Bart., K. C. B.
32	Greece	IV	. . . .
33	Guatemala	V	J. Montefiore, Consul General.
34	Haïti	. .	. . . .
35	Hungary	I	. . . .
36	Italy	I	His Exc. Edoardo Pantano, Senator, Presid. of the Instit.
37	Eritrea & It. Somalia	IV	Prof. G De Michelis, Gen. Commissioner of Emigration.
38	Tripoli and Cirenaica	IV	Count Edoardo Soderini.
39	Japan	I	Minoru Fujii, Secretary to the Embassy.
40	Latvia	V	Dr. M. Walters, Minister Plenipotentiary.
41	Luxembourg	V	O. Bolle.
42	Mexico	III	. . . .
43	Montenegro	V	G. Volpi, Minister Plenipotentiary.
44	Netherlands	IV	Dr. J. J. L. van Rijn, Commercial Attaché to the Legation.
45	Dutch East Indies	IV	Dr. J. J. L. van Rijn.
46	Nicaragua	V	V. E. Bianchi, Consul General.
47	Norway	IV	A. Fjelstad, Counsellor to the Agricultural Department.
48	Ottoman Empire	I	Dr. Mehmed Djémil Bey.
49	Paraguay	V	. . . .
50	Persia	V	A. del Gallo, Marquis of Roccagiovine.
51	Peru	V	Prof. E. P. Molinatti.
52	Poland	IV	B. Janiszowski, Consul General.
53	Portugal	IV	Eusebio Leão, Minister Plenipotentiary.
54	Roumania	I	N. Dianu, Counsellor to the Legation.
55	Russia	I	His Exc. G. Zabiello, Consul General.
56	San Marino	V	His Exc. L. Luzzatti, Minister of State.
57	Kingdom of the Serbs, Croats and Slovenes.	III	C. Scotti, Consul General.
58	Spain	I	Francisco Bilbao y Sevilla, Agricultural Engineer.
59	Sweden	IV	Baron C. N. D. de Bildt, Counsellor to the Legation.
60	Switzerland	IV	Georges Wagnière, Minister Plenipotentiary.
61	United States	I	Prof. Asher Hobson.
62	Uruguay	V	Enrique J. Rovira, Consul.

General Secretary: Prof. **Carlo Dragoni.**

EDITORIAL STAFF OF THE BUREAU OF AGRICULTURAL INTELLIGENCE AND PLANT DISEASES

Chief of Bureau: Dr. **Jules Michel Saulnier**

Editors:

Dr. Guido Borghesani, Chief Rédacteur
Prof. Giulio Trinchieri, Chief Rédacteur
Prof. Girolamo Azzi
Théodore Biéler, Lic. ès Sc. phys. et nat

Dr. Francesca Pirazzoli
Dr. Giulio Provinzal
Margarite L. Yeo, Dipl. Hort. Sc. (Oxford & Reading).

PREFACE

This Index though arranged alphabetically retains the grouping of the subjects used in the *International Review.*

Except in the case of the original articles, which are numbered according to their pages, the numbers of each subject refer to the paragraphs in the *Review.*

The Index consists of three parts: one of the original articles, one concerned with Agricultural Intelligence and the last with Plant Diseases.

In case of errors in the *Review* with reference to scientific terms. and the names of authors, it should be noted that the correct spelling can be relied upon in the Index.

The Table used for the conversion of the Weights, Measures and Money values of the various countries to the Metric System is included.

This Index was prepared by rédacteurs: Dr. Giulio Provenzal and Prof. Giulio Trinchieri, the latter compiled the Index of Plant Diseases. The whole was adapted to the English Edition by rédactrice Miss M. L. Yeo.

I. — INDEX OF ORIGINAL ARTICLES

Benlloch Miguel: Motorculture in Spain, *page* 1220.
Brunel M. The Agricultural Institute of Algeria, *page* 659.
De Vuyst Jeanne: A High School of Rural Household Economy in Belgium, *page* 1217.
Krosby: Organisation of Agricultural Book-Keeping in Norway, *page* 795.
Perris G.: Description of Valuable Chinese Books presented to the Library of the International Institute of Agriculture, *page* 1067.

II. — AGRICULTURAL INTELLIGENCE

A) INDEX OF SUBJECTS.

Abaca (*Musa textilis*): Its Cultivation in Philippines, 1108.
Abies lasiocarpa and *A. concolor:* Effect of Late Spring Frost on its Vegetation, 472.
Abies spp., 472, 498, 733.
Abramis brama, 1153.
Abutilon indicum, 392.
Acacia: The Digestibility Coefficients in Leaves, Twigs and Small Branches, 526. *Acacia* spp., 292, 630, 726, 1122.
Acanthopanax ricinifolium, 732.
Acer campestre, 472.
Acer Negundo, 148, 472, 732.
Acer spp., 361, 526, 733, 884.
Aceras anthropophora, 1122.
Acerina cernua, 1153.
Achras Sapota, 57, 298, 637.
Acorns: Industrial Alcoholic Production, 764.
Actaea spp., 67, 367.
Adathoda vasica, 383.
Adlay, *Coix Lacrima-Jobi*, var. *mayuen*, 625.
Aesculus Hippocastanum, 361, 526, 733, 884, 1100.
Africa: Nitrogenous Fertiliser Industry, 890.
Africa French West: Goats, 83. Botanical Exploration, 371. Tsétsé flies, 360. Goat Coccidiosis, 525. Cattle, 741.
Africa, North: Phosphate of Lime, 19. See Morocco, Algeria, Tunisia, Egypt.

Africa, South: The Angora Goat, 83. Plants as Paper-Making Materials, 498. Tea Trade in South Africa, 631. Cotton Growing in Natal, 908. Consumption of Sodium Nitrate, 988. Hop-Growing Experiments in South Africa, 1007. Citrus Fruits Cultivation in Rhodesia, 1011.

Agave, 389, 1045.

Agricultural Education: Agricultural Instruction in the Former Austro-Hungarian Empire during the war, 5. Domestic Economy and Agricultural Schools for Girls in Italy, 6. British Empire Forestry Education, 166. The Agricultural Institute of Algeria, *page* 659. A High School of Rural Household Economy in Belgium, *page* 1217. Scientific and Agricultural Instruction in Brazil, 1078.

Agrostemma Githago, 67.

Albizzia Julibrissin, 732.

Alburnus lucidus, 1153.

Alcohol: From the Prickly Pear (*Opuntia vulgaris* and *O. amylacea*), 430. Raw Materials for Industrial Alcoholic Production, Sugar Beet, Prickly Pear, Molasses, Potatoes, Sweet Potatoes, Maize, Acorns, Straw and Sawdust, 764. The Industrial Manufacture from Carobs, 1044. From the Agave, 1045. From Potatoes, 1047. Production and Exports in Austria and in Czecho-Slovakia, 1194.

Alfalfa, see Lucerne.

Algeria: The Goats of the Mediterranean Countries, 83. The Agricultural Institute, *page* 659 Sheep Breeding, 541. Aromatic Plants, 1122. Trials of Foreign Cereals, 1212.

Allium Cepa, 262.

Almond: Some Nutritive Properties of the Almonds, 4. Copper Content in Sweet and Bitter Almonds, 475. Soil Ingredients in Fresh Fruits, 598. Use of the Ash of the Husks of Almonds, 802.

Alnus glutinosa, 472, 526, 733.

Aloe dichotoma, 498.

Aluminium as a Factor in Soil Acidity, 366.

American Aspen, *Populus tremuloides*, 367, 472.

American Burnet, *Sanguisorba canadensis*, 367.

American Cranberry, *Vaccinium macrocarpon*, 367.

Amino-Acids from the Globulin of *Cocos nucifera*, 264.

Ammonification, see Manures, Nitrogenous, Soil Microbiology, Soil.

Amphicarpa monoica, 367.

Analysis of Agricultural Products: Soil Analysis as a Means of Measuring Fertility, 14. Protein in Different Oil-Cakes, 76. Composition of Some Wintering Rations for Steers, 81. Coprah Cake Composition, 77 Lupins, Composition before and after Sweetening, 119. Cohune Nut. Composition, 120. Brazilian Manioc, 155. Wheat Composition, 202. Indication of the Degree of Bolting of the Flour by Hydrogen Peroxide, 203. Castor-oil Beans Composition, 205. The Moisture Equivalent and the Analysis of the Soil, 250. Research on the Diffusion of Sulphocyanic Acid in Plants, 262. Some Proteins from the Georgia Velvet Bean, the Mungo Bean, and the Coconut, 263, 264. Analysis of the "Cignarellone" Wheat of Molise, Italy, 283. Compared Composition of Sunflower and Maize Silage, 280. Centesimal Composition of some Cereals, 385. Chemical Composition of *Solanum bullatum* and *S. grandiflorum*, 386. Analysis of the Apricot Kernels, and Characteristics of the Apricot and Almond

Fixed Oils, 432. Composition of Cantaloup Seed Oil, 433. Analysis and Composition of Tomato-Seed Oil, and Seed Cake, 434. Estimation of Added Water in Milk Analysis, 438 Measurement of the Fat-Content of Cheese, 439. The Presence of Copper in Various Plants, 475. Analysis of *Saccharum biflorum*, 495. Chemical Composition of the Seeds of *Prunus brigantiaca* and their Oil, 499. Composition of the Resin, from *Boswellia serrata*, *Cercidium spinosum* and *Xanthorrhoea* spp., 501. Analysis of the Cinnamon Bark, 502 Buchu Resin and Oil Composition (*Barosma betulina*), 503. Tomato Composition Changes during Ripening, 505. French Fish-Meal Composition, 543, 738. " Pig Meal " and " Pig Compo " Composition, 544. Composition of Material produced by Wet and Dry Processes of Degerminating Maize, 555. Soil Ingredients Withdrawn by Various Fresh Fruits, 598. Distribution of Titanium Dioxide in Various Plants and Soils, 599. Plant Analysis in Relation to Manuring, 603. Analysis of Adlay (*Coix Lacryma-Jobi* var. *mayuen*) for Comparison with Various Grains and Pulses, 625. Analysis of the Curua Palm Fruits and Meal, 627. Analysis of Prickly Pear Seeds, 628. Centesimal Composition of the Breadfruit (*Artocarpus communis* L.), Banana and Mango Fruits, 638. Average Composition of " Lagmi ", 672. Analysis of the *Atriplex Halimus* Ashes, 705. Sweet Maize Composition, 708. Chemical Composition of the Sweet Potatoes from Different Countries, 719. Analysis of the Pods and Seeds of *Prosopis Stephaniana*, 720. Analysis of the Ashes of the Green Husk of Almonds, 802. Analysis of the Ashes of Saltbushes, 807. Percentage Composition in Digestible Matters of the two Brazilian Forages, *Panicum minutiflorum* and *Andropogon rufus*, 816. Composition of Rhizomes and Fronds of Bracken (*Pteris aquilina*), 920. Note on Analysis of Soils, 983. Comparative Study of the Composition of the Sunflower and Maize Plants at Different Stages of Growth, 1003. Percentage Composition of Oat, 1099. Hemp Stalks, Chemical Composition, 1121. Digestive Nutrient Substances in Wheat Straws, 1135. Analysis of Musts of Sound Grapes and of Grapes Infected with Eudemis, 1166 Analyses of Ox-foot and Sheeps-foot Oils, 1173. Analysis of Napier Grass (*Pennisetum purpureum*) Compared with Green Maize Fodder, 1217. Chemical Composition and Food Value of *Monilia coerulea* Hay, Experiments made in Germany, 147. Studies in Milk Analysis, 1278. Determination of Watering and Skimming on Samples of Altered Milk, 1283.

III — PLANT DISEASES

A) INDEX OF SUBJECTS.

ABACA (*Musa textilis*): Resistant to *Fusarium cubense*, in the Philippines, 459

Abella subflava: On *Eutettix tenella* in Idaho and California, 588

Abies grandis: *Thelephora terrestris* in U. S. A., 869.

Ablerus perspeciosus: On *Aulacaspis pentagona* in Japan, 1185.

Acacia mollissima: *Acanthopsyche junodi* and Natural Enemies in Natal, 1186.

Acanthopsyche junodi: On *Acacia mollissima* in Natal, and its Nat. Enemies, 1186

Acanthoscelides obtectus: On Beans in Austria, 586

Acer macrophyllum and *A. Negundo*: *Thelephora terrestris* in U. S. A., 869.

Acrospeira mirabilis, 768.

Adomonita demylus: On *Neodiprion lecontei* in U. S. A., 786.

Adonis vernalis: *Amphicoma vulpes* in Crimea, 784

Aedemoses haesitans: In Texas, 870.

Aelothrips albocinctus and *Ael. fasciatus*: On Soya Beans in Baden (Germany), 1191

Africa: New Weevils injurious to Cultivated Plants, 348

Africa, South: Diseases of Cultivated Plants in Cape Province, 957. Natural Enemies of *Acanthopsyche junodi* on *Acacia mollissima* in Natal, 1186 *Phyllosticta Caricae-Papayae* on Paw-paw in Natal, 1064 *Septogloeum Arachidis* on Peanut, 342 *Silvestrina silvestrii* on *Morus alba* in Capetown and on *Olea verrucosa* in Natal, 239 Tobacco Slug (*Lema bilineata*), 354.

Agallia, 588

Agaricus melleus: On Weymouth Pine in Switzerland, 1193

Agave: *A. americana*, *A. rigida*, *A. Salmiana* attacked by *Colletotrichum Agaves* in Indo-China, French Sudan, and France, *A. applanata*, resistant to *Coll. Agaves* in France; *Agave* sp. attacked by *Gloeosporium Agaves* in Brazil, 1061

Agriolimax agrestis: On Soya Bean in Baden (Germany), 1191.

Agriotes lineatus: On Soya Bean in Baden, 1191.

Agropyron repens: Eradication in Canada, 579.

Ailanthus glandulosa. *Attacus cynthia*, 1971.

Alabama: *Bacterium Solanacearum* on Castor Plant, 1061.

Alabama argillacea: In Texas, 870. On Cotton in Brazil, 1306.

Alcides leucogrammus: On Beans and *Vigna Catjang* in Rhodesia, 352.
Aleurocanthus woglumi: On Citrus Fruits etc. in Cuba, 955.
Aleurodicus cocois: On Coconut in Porto Rico, 1307.
Aleyrodes citri: Importation suspended into Italy of infected citrus fruits, 443.
Alfalfa see Lucerne.
Algeria: Resistance of Cereals to Rust, 1212.
"Allens Everlasting". Apple Var. Immune to Spotting, 108.
Allessatura (Scald): Of Citrus Fruits in S. Italy, 860.
All Head Early: Cabbage Var. Resistant to *Fusarium conglutinans* in U. S. A., 338.
Allington Pippin: Var. Apple liable to Spotting in England, 108.
Almond: *Fomes fulvus* in Italy, 577. Bacterial Diseases in Morocco, 862.
Alternaria: *A. Grossulariae* and *A. pomicola*, possible causes of Spotting of Apples, 108. *A. Nelumbii* on *Nelumbium speciosum* in U. S. A., 778. *A. Solani* on Tomato in Victoria, 107. *A. tenuis* on *Aucuba japonica* in Italy, 552.
Althaea officinalis: *Aulacaspis rosae* and *Heterodera radicicola* in Italy, 552.
Amaranthus: *A. deflexus*, Newly Recorded Weed in New South Wales, 1182. *A. macrocarpus*, 1182. *Amaranthus* sp. host of *Ceroplastes sinensis*, 465.
America, North: *Rhagium lineatum* on Pines, 785.
Amorbia emigratella: in Texas, 870.
Amphicoma vulpes: On *Adonis vernalis* in Crimea, 784.
Anagrus giraulti: Parasite of *Eutettix tenella* in Idaho and California, 588.
Andropogon: *A. intermedius*: *Claviceps* sp. in Australia, 960. *A. Sorghum*: *Sclerospora philippinensis* in Philippines, 686.
Anguillulidae, 575.
Anomis erosa and *A. exacta*: In Texas, 870.
Anona: *Euthyrrhinus meditabundus* in Australia, 970.
Anthonomus: *A. cinctus* and *A. pomorum* (= *A. pyri* and *A. bituberculatus*) on Apples in Great Britain, 1192. See also Weevil.
Anthracnose: Resistance of Nosiola Trentino white Grape Vine, 728. A. of Sisal Hemp (*Colletotrichum Agaves*), 1061.
Anuraphis fasciatus: On Lucerne in Italy, 347.
Anuriella dorsolineata: In Italy, 347.
Aonidiella: *A aurantii*: *Rhizobius lophantae*, 580. *A. perniciosa*, see San José Scale.
Aphelinus: *A. fuscipennis*, Parasite of *Aspidiotus perniciosus* and *Chionaspis* sp. in Japan; *A. japonicus*; *A. mytilaspidis* on *Hemichionaspis aspidistrae* in Japan, 1185. *A. mali*: Importation and Acclimatisation in Uruguay and Parasite on Woolly Aphis (*Eriosoma lanigera*), 692.
Aphicus sp.: Nat. Enemy of *Ceroplastes sinensis*, 465.
Aphids: New species discovered in Italy, 347.
Aphis: *A. gossypii* on Cotton in Brazil, 1306. *A. maydis*, Means of Dispersing Mosaic Disease of Maize, 99. *A. rumicis* (= *A. euonymi*, *A. fabae*, *A. papaveris*). Biological Studies, 964. See also Woolly Aphis.
Apion longirostre and *A validum*: On Hollyhock in Crimea, 784.
Aplastomorpha vandinei: On *Sitophilus oryza* in U. S. A., 463.
Apples: *Anthonomus cinctus* and *A. pomorum* in Great Britain, 1192. *Aphelinus mali*, Importation and Acclimatisation in Uruguay and

Parasite of Woolly Aphis (*Eriosoma lanigera*), 692. *Cacoecia franciscana* in California, 697. *Ceroplastes sinensis* (?), 465. *Rhabdopterus picipes* on Grimes Golden Var. in N. Y. State, 356. Spotting in England, 108. *Trichothecium roseum* in Italy, 779.

Archenomus orientalis: On *Aulacaspis pentagona* in Japan, 1185.

Areca Catechu: *Coccotrypes dactyliperda*, 580.

Argentina: *Cuscuta racemosa* on Lucerne, 1069. *Gyropsylla ilicicola* on Mate, 1309. *Phalaris bulbosa*: Resistent to Disease, 1215.

Arion hortensis: On Soya Bean in Baden (Germany), 1191.

Armillaria mellea: On Weymouth Pine in Switzerland, 1193.

Arolle (*Pinus Cembra*), 1193.

"Arrabbiaticcio" ("Terre-Gatée"). Researches in Italy, 230.

Arsine: As Fungicide and Insecticide, 462.

Artichokes: Pests in Italy, 60.

Arvicola arvalis: On Soya Bean in Baden (Germany), 1191.

Ascochyta Pisi: On Leguminosae in Morocco, 862.

Asia: Curculionidae on Cultivated Plants, 348.

Aspergillus flavus: Nat. Enemy of *Pseudococcus* sp. in Cuba, 782.

Aspidiotus: *A destructor* on Coconut in Porto Rico, 1307. *A. perniciosus* Host of *Aphelinus fuscipennis* in Japan, 1185.

Aster formosissimus: *Ceroplastes sinensis*, 465.

Asterocystis radicis: On Flax in Morocco, 862.

Atanycolus simplex: On *Rhagium lineatum* in N. America, 785.

Athene brama: Useful Bird in India, 111.

Atriplex spp.: *Eutettix tenella* in Idaho and California, 588.

Atropa Belladonna: *Macrosporium Solani* and *Thielavia basicola* in Italy, 452. *Epithrix atropae*, *E. pubescens*, *Psylliodes hyoscyami*, *Mamestra brassicae*, *Heliothis peltigera* in Crimea, 84.

Attacus cynthia: Observations on Polyphagous Nature, 1071.

Attidae: Feeding on *Oncopera mitocera* in Queensland, 1190.

Aucuba japonica: *Pleospora infectoria* var. *aucubicola* in Italy, 688.

Aulacaspis: *A. pentagona* Host of *Ablerus perspeciosus*, *Archenomus orientalis*, *Azotus capensis*, *A. chionaspidis*, *Perissopterus mexicanus*, *Prospaltella berlesei* and *P. nigatae* in Japan, 1185. *A. rosae* on *Althaea officinalis* in Italy, 452.

Australia: Ergot (*Claviceps* sp.) on Grasses, 960. *Euthyrrhinus meditabundus* on *Anona*, Mango, *Poinciana*, 970. *E. m.* Parasitised by *Chalcis euthyrrhini*, 965, 970. By *Thaumasura curculionis* and *Th. pavo*, 970. *Oncopera mitocera*, New Grass Pest in Queensland, 1190. *Pulvinaria ornata*, on Citrus Fruits and *Pittosporum undulatum* in New South Wales, 968. *Tylenchus* sp. on Banana in North Queensland, 466.

Austria: *Acanthoscelides obtectus* on Beans, 586.

Avocado: *Gracilaria perseae* in Florida, 240.

Azotus capensis: On *Aulacaspis pentagona* and *A. chionaspidis* on *Chionaspis difficilis* and *Aul. pentagona* in Japan, 1185.

BACILLUS: *B. Aroideae* on *Calla aethiopica* (= *Richardia africana*), 575. *B. Solanacearum* on Tomato in Victoria, 107.

Bacteria, Anaerobic, and Gummosis: Of Walnut in France, 343.

Bacterial Blackrot (*Bacterium campestre*), 338.

Bacterial Disease: Of Stone Fruits (*Pseudomonas Pruni*), 1297.

Bacterial Wilt: of Tomato (*Bacillus Solanacearum*), 107.

Bacteriosis: of Ivy in France, 457. Of *Richardia* in England, 575.

Bacterium: *B. exitiosum* on Tomato in U. S. A., 867. *B. marginatum* on *Gladiolus* spp. in District of Columbia and in Illinois, 1066. *B. Solanacearum* on Castor Plant in Georgia, Florida and Alabama; Inoculated succesfully into Tomato, *Datura Stramonium*, Cotton, *Tropaeolum majus*, Sunflower, Balsam, Fuchsia, Vanilla, 1062. *B. translucens*, var. *undulosum*, 572. See also Gumming.

Bactrocera cucurbitae: Host of *Opius fletcheri* in Hawaii, 349.

Baden: Pests of Soya Beans, 1191.

Bagisara rectifascia: In Texas, 870.

Baits, Poisoned: For Crickets, 112.

Baliothrips dispar: On Soya Beans, 1191.

Balm: *Cassida viridis* and *Cryptocephalus ocellatus* in Crimea, 784.

Bamboo: *Chlorophorus annularis* and Nat. Enemies in Tonkin, 1075.

Banana: *Fusarium cubense* on Var. "Latundan" in the Philippines, 459. Panama Disease in Cuba, 955. *Stenommatus musae* in Hawaii, 348. *Tylenchus* sp. in N. Queensland, 466.

Barbados: *Ovulariopsis Gossypii* and *O. obclavata* on *Gossypium barbadense* and *Tecoma leucoxylon* respectively, 231.

Baris nitens: On Hollyhock in Crimea, 784.

Barium Carbonate: Toxicity to Rats, 357.

Barley: Seed Coat Injury and Viability as Factors in Susceptibility to Moulds and Fungicides, 863. *Heterodera schachtii* and *Helminthosporium gramineum*: Resistance to, in Sweden, 144. *Puccinia graminis* and *P. glumarum* in Morocco, 862. Wild Barley: *Tetraneura flavescens* in Italy, 347. *Ustilago nuda* and *U. Hordei* in Morocco, 862. Varieties Resistant to Disease in Manhndorf (Germany), 478.

Barnack Beauty; Apple Var. Immune to Spotting, 108.

Beans: *Acanthoscelides obtectus* in Austria, 586. *Alcides leucogrammus* in Rhodesia, 352. *Aphis rumicis*, 964. *Ceroplastes sinensis*, 465. Resistance to Disease in N. Y. State, 377. *Spermophagus pectoralis* in California, 689. *Sp. subfasciatus*, 580. *Uromyces appendiculatus* and *U. Fabae* in Morocco, 862.

Bean Weevil, 352, 586, 689.

Beet: *Phthorimaea* (*Lita*) *ocellatella* in Germany, 1308.

Beet, Sugar: *Eutettix tenella* in Idaho and California, 588.

Begonia tuberosa: *Otiorrhynchus sulcatus* and *Hoplisus laticinctus* in France, 237.

Behar (India): Wilt Disease of Indigo (*Indigofera arrecta*), 1057.

Belgium: Fruit Fungi, 567. Inoculation Experiments on Caterpillars of *Pieris rapae* and an Adult of *Locusta viridissima* with *Micrococcus* (*Staphylococcus*) *acridicida*, 1184.

Belladonna: See *Atropa Belladonna*.

Belle Dubois, Apple var. Immune to Spotting, 108.

Bengal: *Hoplocerambyx spinicornis* on *Shorea robusta*, 583.

Birch: *Ctenophora atrata* in Switzerland, 876.

Birds: In India: Useful in Agriculture: — *Athene brama*, 111. *Brachypternus aurantius*, 583. *Dicrurus macrocercus*, 966. Birds harmful to Cacao in the Dominican Republic, 1076. Nat. Enemy of *Acantho-*

psyche junodi, in Natal, 1186.
Black Aphis (*Aphis rumicis*), 964.
Black Chaff of Wheat (*Bacterium translucens* var. *undulosum*), 572.
Black Drongo (*Dicrurus macrocercus*), 966.
Black Rot of Grapes (*Guignardia Bidwelli*); Prohibitive Measures concerning Importation of Fruits into Italy, 443. B. r. in the Caucasus (*Macrophoma reniformis*), 1297.
Black Scab, of Potatoes (*Synchytrium endobioticum*). Prohibitive Measures concerning Importation of Tubers into Italy, 443.
Black Spot, of Plum (*Pseudomonas Pruni*), 1297.
Black Wattle (*Acacia mollissima*), 1186.
Blight. See *Phytophthora*.
Bocchoris pharaxalis: On Cacao in the Dominican Republic, 1076.
Boll Disease, Cotton: In St. Vincent, West Indies, 1004.
Bollworm, Cotton: In Cambodia, Means of Control, 1221.
Bombax insigne: *Gloeosporium Bombacis* in Brazil, 576.
"Bombyx cul-brun" (*Euproctis chrysorrhoea*), 694.
Bordeaux Powder: Control of Vine Mildew, 1058.
Borers, Cane: In Brit. Guiana, 1183.
Borers, Maize: *Pyrausta nubilalis*, 585, 783.
Borkhausenia diveni: In Texas, 879.
Botrytis, 1007. *B. Bassiana*: On Various Insects, 844. *B. Douglasii* on *Pseudotsuga Douglasii* in Scotland, 346. *B. D.* on *Ps. Douglasii* in England and Scotland, 1300. *B. galanthina* on *Galanthus* spp. in England, 456.
Brachypternus aurantius: Useful Bird in India, 483.
Brachystegia spp.: *Isaniris ater* in S. Rhodesia and Nyasaland, 348.
Brachytrypes sp.: Destroyed by *Athene brama* in India, 111.
Bramble Leaf, of Vine in Tripolitania, 1174.
Bramley's Seedling: Apple Var. Liable to Spotting in England, 108.
Brassolis sophorae: On Coconuts in Brit. Guiana, 1183.
Brazil: Cotton Diseases, 700, and Pests, 1306. Control of Diseases in S. Paolo, 1220. *Gloeosporium Agaves* on *Agave* sp., 1061. *Gl. Bombacis* on *Bombax insigne*, 576. *Silvestrina silvestrii* on *Morus alba* in S. Paolo, 239. Vine Diseases and Pests in Rio Grande do Sul, 301. Wheat: Diseases in Parana, 285.
Bretonnières: Wheat in Swiss Jura Resistant to Rust, 617.
Bróca, Cotton (*Gasterocercodes gossypii*), 1306.
Bromus: *B. commutatus*: *Sclerospora macrospora* in Tennessee and Kentucky, 1059. *B. inermis*: *Claviceps* sp. in Australia, 960.
Bruchidius obtectus: See *Acanthoscelides obtectus*, 586.
Buckwheat (*Fagopyrum Fagopyrum*): *Pyrausta ainslei*, 783.
Bunt (*Tilletia Tritici*), 449.
Bureau: Imperial Bureau of Mycology, London, 566. Bureau of "Sanidad vegetal" of Cuba, Organisation and Development, 955.

CABBAGE: *Ceutorrhynchus quadridens* (Seed Stalk Weevil) in Long Island, N. Y. State, 1310. *Fusarium conglutinans*, Resistant Vars. in U. S. A., 338.
Cacao: "Calabacillo" Resistant to Disease in Dominica, 596. Fungous Diseases in Brit. Guiana, 1193. Animal Pests in Dominican Republic, 1076.
Cacoecia franciscana: On Apples in California, 697.
"Caculo común" (*Phyllophaga portoricensis*).

" Caculo rinoceronte del coco " (*Strategus quadrifoveatus*), 1307.
Calamint: *Eucarazzia picta* in Italy, 347.
Calandra: *C. glandium* bred from Acorns of *Quercus incana* and *Q. dilatata* in India, 348. *C. shoreae* on Seeds of Sal Tree (*Shorea robusta*) and of *Dipterocarpus turbinatus* in Mauritius and India, 348.
California: *Cacoecia franciscana* on Apples: *Pandemis pyrusana*; *Peronea* sp., 697. *Eutettix tenella* on Sugar Beet, 588. Injurious Insects, 689. *Nicotiana glauca*: *Peronospora Hyoscyami*, 687. *Tipula quaylii* and *T. simplex* on Grass Land, Cereals and Lucerne, 873.
Calla aethiopica (= *Richardia africana*): *Bacillus Aroideae*, 575.
Callida decora: Feeding on *Pyrausta ainsliei* in U. S. A., 783.
Calosoma sycophanta: Nat. Enemy of *Stilpnotia salicis* in Massachusetts and New Hampshire, 877.
Calotropis procera: *Dacus longistylus* in Egypt, 581.
Camarosporium cruciatum, 233.
Cambodia: Control Methods recommended for Cotton Stem Weevil and Bollworm, 1221.
Campanula rapunculoides: *Clathrosorus Campanulae* in Denmark, 460.
Camphor: Diseases and Pests in Federated Malay States, 951.
Canada: *Hemerocampa pseudotsugata* on *Pseudotsuga Douglasii* in Brit. Columbia, 590. *Pyrausta nubilalis* on Maize and *Stilpnotia salicis* on Poplars, 585. *Rhagium lineatum* on Pines, 485. Weed Control Measures, 579. Entomological Service, 882.
Canary Grass (*Phalaris minor*): Ergot, 960.
" Canker, American " of Chestnut (*Endothia parasitica*): Suspension of infected Plants imported into Italy, 443.
Cantharides (Spanish Fly) (*Lytta vesicatoria*), 957.
Cape Province: Diseases of cultivated Plants, 951. *Silvestrina silvestrii* on *Morus alba*, in Capetown, 239.
Carcelia evolans: Parasite of *Acanthopsyche junodi* in Natal, 1186.
Carica Papaya: *Phyllosticta Caricae-Papayae*, in Natal, 1064.
Carpophilus dimidiatus: On *Opuntia* spp. and shelled Peanuts in California, 689.
Carthamus tinctorius: Host of Dipteron of Fam. Trypaneidae in Egypt, 581.
Casca chinensis: Parasite of *Chionaspis difficilis* in Japan, 1185.
Cassida viridis: On Larch in Crimea, 784.
Castnia licus: On Sugar Cane in Brit. Guiana, 1183.
Castor Oil: Uredineae in Morocco, 862. *Macrosporium Cavarae* in Italy, 452.
Caucasus: *Macrophoma reniformis*, Cause of Black Rot of Grapes, 1299.
Caudelle (*Tenebroides mauritanicus*), 689.
Cavengire: Sugar Cane Var. fairly resistant to Gumming (*Bacterium vascularum*) at Porto Rico, 105.
Celery: *Pseudomonas Apii* in N. Y. and Michigan States, 868. *Sclerotinia minor* in U. S. A., 574.
Cephaleuros mycoidea: On Tea in Ceylon, 393.
Cephalothecium roseum, 779.
Ceratitis capitata: On Guavas, Oranges, Peaches etc., in Egypt, 581. Host of *Opius fletcheri* in Hawaii, 349.
Cercocephala elegans: On *Sitophilus oryza* in U. S. A., 463.
Cercopidae: On Sugar Cane in Brit. Guiana, 1183.
Cereals: *Nesokia bengalensis* in Goa

(Portuguese India), 878. Rice Weevil (*Sitophilus oryza*), in U. S. A., 463. Rust, Behaviour of Different Varieties in Algeria, 1212. *Tipula quaylii* and *T. simplex* in California, 873.
Ceroplastes : *C. cirripediformis*, 689. *C. rubens*, 1185. *C. sinensis*, 465. *Ceroplastes* spp., 1063.
Ceutorrhynchus : *C. macula-alba* on Capsules of *Papaver somniferum* in Crimea, 784. *C. quadridens* on Cabbage Seed Stalks in Long Island (N. Y. State), 1310.
Ceylon : *Cephaleuros mycoidea* and *Pestalozzia Hartigii* on Tea, 393.
Chaetodacus zonatus : On Mango in Egypt, 581.
Chalcis euthyrrhini : On *Euthyrrhinus meditabundus* in Australia, 965, 970.
Chauliognathus pennsylvanicus : Feeding on *Pyrausta ainsliei* in U. S. A., 783.
Cheimatobia brumata. See *Operophthera brumata*.
Chenopodium sp. : *Eutettix tenella* in Idaho and California, 588.
Chermes cooleyi : On *Pseudotsuga Douglasii* in Grt. Britain, 971.
Cherry : *Attacus cynthia*, 1071.
Cheshunt Compound, 1296.
Chestnut : Decree prohibiting importation into France of Plants, Fruits and Seeds, likely to be infected with *Endothia parasitica*, 565. Prohibitive Measures concerning Importation into Italy, as a guard against *Endothia americana*, 443. *Sclerotinia pseudotuberosa*, Ascophorous Form of *Rhacodiella Castaneae* : Cause of Black Rot, 224. *Spirospora Castaneae* in France, 109. *S. c.* = *Acrospeira mirabilis*, 768.
Chilocorus sp. : Nat. Enemy of *Ceroplastes sinensis*, 465.
China : *Phoma citricarpa* on *Citrus nobilis* and *C. sinensis*, 780.
" Chinche harinosa " (*Pseudococcus nipae*), 1307.
" Chinotto " (*Citrus sinensis*) : *Ceroplastes sinensis*, 465.
Chionaspis : *C. difficilis*, Host of *Azotus chionaspidis* in Japan, 1185. *Chionaspis* sp. : Host of *Aphelinus fuscipennis* in Japan, 1185.
Chlorophorus annularis, Nat. Enemies of this Coleopteron in Tonkin, 1075.
Chloropicrin : As Insecticide, 265, 462. Control of Crickets at Crau, 112. Control of Termites, 114.
Chlorosis : Of Plum in S. Africa, 937.
Christmas Pearmain, Apple Var. Immune to Spotting, 108.
Chrysanthemum : *Rhopalosiphum trilineatum* in Italy, 347. Rust (*Puccinia Chrysanthemi*) in S. Africa, 957.
Chrysanthemum frutescens and *Chrys. grandiflorum* : *Ceroplastes sinensis*, 465.
Chrysomphalus dictyospermi : On *Cinnamomum Camphora* in Italy, 452. On *Kentia* spp. and *Persea gratissima* in California, 689.
Chrysophlyctis endobiotica : See *Synchytrium endobioticum*.
Cicadula 6-notata, 588.
Cigarette Beetle (*Lasioderma serricorne*), 689.
Cignarellone, Wheat Var. Resistant to Rust, Lodging, 283.
Cinnamomum Camphora : *Chrysomphalus dictyospermi* in Italy, 452.
Citrus Fruits : *Aleurocanthus woglumi* in Cuba, 955. *Ceroplastes cirripediformis* in California, 689. *Ceroplastes sinensis* in Italy and France, 465. *Citrus grandis* and *C. mitis* : *Pseudomonas Citri*, 445. *C. nobilis* and *C. sinensis* : *Phoma citricarpa* in China, 780. Coccids of Citrus Fruits in Brit. Guiana, 1183. Diseases and Pests in U. S. A., Porto Rico and India, 1011. In Tunisià, 395, *Isaniris ater* in S. Rho

desia and in Nyasaland, 348. *Lepidosaphes gloverii* and *Aleyrodes citri*, Cause of Suspension of Importation of Fruits into Italy, 443. *Pantomorus* (*Aramigus*) *fulleri*, 580. *Pulvinaria ornata* in New South Wales, 968. "Scald" in S. Italy, 860.
Citrus Canker (*Pseudomonas Citri*), 445.
Clathrosorus Campanulae: On *Campanula rapunculoides* in Denmark, 460.
Claviceps sp.: On Grasses. in Australia, 960.
Clover: *Gloeosporium caulivorum* in Morocco, 862.
Club-Root (*Plasmodiophora Brassicae*), 338.
Cluster Rot of Vine, 1299.
Clydonopteron tecomae: In Texas, 870.
Coccophagus lecanii: On *Ceroplastes rubens*, *Phenacoccus pergandei*, and *Pulvinaria citricola*: *C. yoshidae* Parasite of *Coccus hesperidum* in Japan. 1185.
Coccotrypes dactyliperda: In Latium 580.
Coccus hesperidum: Host of *Coccophagus yoshidae* in Japan, 1185.
Cockchafer, Adult: Resistant to Low and High Temperatures, 1072.
Cockleburr, Common (*Xanthium commune*), 1182.
Coconut: *Brassolis sophorae* in Brit. Guiana, 1183. *Epimys rufescens* in Goa, Portuguese India, 878. Injurious Insects in Porto Rico, 912, 1307. *Oryctes rhinoceros* and *Rhynchophorus ferrugineus* in Goa, Portuguese India, 969. "Pudrición del cogollo" Coconut, Bud Rot, in Cuba, 955.
Coffee: *Rosellinia* sp. in Porto Rico, 866. *Systates chirindensis* in S. Rhodesia, 348. *Xylotrechus quadripes* and its Nat. Enemies in Tonkin, 1075.
Colaspis sp.: On Cotton in Brazil, 1306.
Collembola, 575.
Colletotrichum: *C. Agaves* on *Agave* spp. in Indochina, French Sudan and France, 1061. *C. falcatum*: On Sugar Cane in India, 446.
Columbia: Uredinae on *Sarache edulis*, 444.
Columbia, British: *Hemerocampa pseudotsugata* on *Pseudotsuga Douglasii*, 590.
Columbia, District of: *Bacterium marginatum* on *Gladiolus* spp., 1066.
"Comején" (*Eutermes morio*), 1307.
Compsilura concinnata: Nat. Enemy of *Stilpnotia salicis* in Massachusetts and New Hampshire, 877.
Conventions: International Convention for Control of Locusts, Rome, Oct. 31, 1920, 221. Phytopathological Services of Uruguay and International Phytopathological Convention of Rome, 335.
"Copenhagen Market": Var. Cabbage resistant to *Fusarium conglutinans* in U. S. A., 338.
Copper Compounds: Copper Sulphate in Control of Field Poppy in Wheat Fields, 963. Decomposition of Copper Fungicides on Surface of Vine Leaves, 1058. Copper in Anticryptogamic Mixtures, 340. See also Paris Green.
Copra: *Lasioderma serricorne*, *Necrobia rufipes*, *Silvanus surinamensis*, *Tribolium castaneum*, in California, 689.
Coptotermes heimi: On *Dalbergia Sissoo* tapped by Woodpecker (*Brachypternus aurantius*) in India, 583.
Cordiceps sp.: On *Diatraea saccharalis* in Brit. Guiana, 1183.
Coryneum foliicolum: On Apples disfigured by Spotting in England, 108.
Costa Rica: *Puccinia Pittieriana* on Potato and *Puccinia* sp. on *Sarache* sp., 444.

Cotoneaster horizontalis, *C. microphylla*: *Mineola indiginella* in New Jersey, 875.

Cotton: *Anthonomus grandis* (Stem Weevil): On Cambodian Cotton, 1221. Resistant Vars. in the Philippines, 722. *Bacterium Solanacearum*, 1062. Control Methods: Of Parasites in Brazil (São Paolo) 1220. Of Stem Weevil and Bollworm in Cambodia, 1221. Disinfection of Cotton Seed by Means of Dry Heat, 115. Diseases (General): In Brazil, 700. In St. Vincent (W. Indies), 1004. In U. S. A., 388. Injurious Insects: In Brazil, 1306. In U. S. A., 388. *Pectinophora gossypiella* (= *Gelechia gossypiella* = *Platyedra gossypiella*): In Montserrat and St. Kitts (W. Indies), 587. Lepidoptera in Texas likely to be confused with *P. g.*, 870. Machines for Treating Cotton Seed against *P. g.*, 1160. Recorded for the First Time in Porto Rico, 1305. " Red Leaf " prevalent where Potash lacking in St. Vincent (W. Indies), 1004.

Cotton Seed Oil: Effect of Pink Bollworm on Oil Percentage, 671.

Couch Grass (*Pentaphis viridescens*), 347.

Cow Pea (*Vigna Catjang*), 352.

Cox's Orange Pippin: Apple Var. Liable to Spotting in England, 108.

Crane Fly (*Tipula simplex* and *T. quaylii*) in Pastures, Grain and Lucerne in California, 873.

Crau: Control of Moroccan Cricket (*Dociostaurus maroccanus*), 112.

Cremastus facilis: On *Pyrausta ainsliei* in U. S. A., 783.

Crickets, Moroccan (*Dociostaurus maroccanus*): Control Methods, 112. See also Locusts.

Crimea: Insects injurious to Medicinal Plants, 784.

Crocidosema plebeiana: In Texas, 870.

Cronartium ribicola: On Weymouth Pine in Switzerland, 1193.

Crotalaria juncea, 446, 1057.

Crotophaga ani: Nat. Enemy of *Castnia licus* in Brit. Guiana, 1183.

Cruciferae: *Pemphigus populi-transversus* in New Zealand, 241.

Cryptocephalus ocellatus: On Larch in Crimea, 784.

Cryptolaemus montrouzieri: As Nat. Enemy of *Pseudococcus* in Cuba, 782. Feeding on *Pseudococcus* introduced into S. France, 1079.

" Crystallina ": Sugar Cane Var. Subject to Gumming in Porto Rico, 105.

Ctenophora atrata: On Birch in Switzerland, 876.

Cuba: *Aleurocanthus woglumi* on Citrus Fruits etc., 955. Bureau of " Sanidad vegetal " (Commission of Plant Health): Organisation and Development, 955. Diseases of Banana and Coco Palm. Mosaic of Sugar Cane, and the Parana Pest, 955. Insects Injurious to Sugar Cane, 782.

Cucurbitaceae: *Opius fletcheri* parasite of *Bactrocera cucurbitae* on different Vars. in Hawai, 399. *Rhagoletis* (*Carpomyia*) *pardalina*, 581.

Cucurbitaria naucosa: On *Ulmus montana* in Canton of Vaud, Switzerland, 233.

Curculionideae: New Weevils injurious to various cultivated plants in Africa, Asia and Oceania, 348.

Curuquerê (*Alabama argillacea*): On Cotton in Brazil, 1306.

Cuscuta racemosa: On Lucerne in Rio Negro, Argentina, 1069.

Cyanogen Chloride: For Fumigation purposes, 462.

Cyamopsis psoraloides: Attacked by Mite in India, 696.

Cynodon Dactylon: *Ustilago Cynodontis* in Morocco, 862.

Cypress: *Phloeosinus* sp. in Mexico, 698.

Cyrenaica: *Earias insulana* var. *anthophilana* on Cotton and Gombo (*Hibiscus esculentus*), 353. Lodging and Smut: " Mogarbia " Wheat Var. resistant, 282.

DACUS: *D. longistylus* on Fruits of *Calotropis procera* in Egypt, 581. *D. oleae* in Green Olives sent from Cyprus to Alexandria, 581.

Dahlia variabilis: *Ceroplastes sinensis*, 464.

Dalbergia Sissoo: Dead Branches Tapped by Woodpecker (*Brachypternus aurantius*) in India, 583.

" Damping off " of Tomatoes. Caused by *Phytophthora cryptogea*, *Phyt. parasitica* and *Rhizoctonia Solani*, 1296. *Pythium de Baryanum*, 107.

Date: Pests in India, In Victoria (Australia), 507.

Datura: *D. fastuosa*, *D. Metel* and *D. Stramonium*: *Macrosporium Solani* in Italy, 452. *D. Stramonium* and *D. Tatula*: *Lema bilineata* in S. Africa, 354.

" Dawson Golden Chaff ": Wheat var. liable to *Urocystis Tritici* in U. S. A., 865.

Degeeria collaris: Parasite of Elm (*Galerucella luteola*) in Italy, 582.

Denmark: *Clathrosorus Campanulae* on *Campanula rapunculoides*, 460.

Diaspis pentagona: *Rhizobius lophantae*, 580.

Diatraea: *D. saccharalis* on Rice; *D. saccharalis* and *D. canella* on Sugar Cane in Brit, Guiana, 1183.

Dicrurus macrocercus: Useful Bird in India, 966.

Dicymolomia julianalis in Texas, 870.

Digitalis purpurea: *Ramularia variabilis* in Italy, 452.

Dioryctria splendidella: On Weymouth Pine in Switzerland, 1193.

Diplodia melanea, 233.

Dipterocarpus: *D. turbinatus*: *Calandra shoreae* in Mauritius and India, 348.

Dociostaurus maroccanus: Control Methods in Crau, 112.

Dominican Republic: Animal Pests of Cacao, 1076.

Dominica (West Indies): " Calabacillo " Cacao var. Resistant to Disease, 596.

Doryctes bistriatus, *D. brevipetiolus*, *D. picticeps*, *D. strioliger* and *D. tristriatus*, Parasites on larvae of *Xylotrechus quadripes* and *Chlorophorus annularis* in Tonkin, 1075.

Dorylus helvolus: Nat. Enemy of *Alcides leucogrammus* in Rhodesia, 352.

Doryphora decemlineata: Suspension of Importation of Potato Tubers etc. into Italy owing to this pest, 443.

Dryopeia hirsuta (closely related to *Dr. bella*): on Rice in the Philippines, 695.

Dumelow's Seedling (Wellington): Apple var. Liable to Spotting in England, 108.

Dupontia cincticornis: on larvae of *Chlorophorus annularis* in Tonkin, 1075.

Dysdercus ruficollis: On Cotton in Brazil, 1306.

EARIAS INSULANA var. *anthophilana*: On Cotton and Gombo (*Hibiscus esculentus*) in Cyrenaica, 353.

" Early May ", Wheat Var. resistant to *Urocystis Tritici* in U. S. A., 865.

" Early Wisconsin Hollander ", Cabbage Var. Resistant to *Fusarium conglutinans* in U. S. A., 338.

Ecklinville Seedling: Apple Var. Liable to Spotting in England, 108.

Ecuador: *Puccinia Pittieriana* on Potato and Tomato, 444.

Egypt: Fruit Flies, 581.

Elaeis guineensis, see Oil Palm.

Endothia parasitica: Decree of Presi-

dent of French Republic of March 8, 1921. prohibiting the importation of living plants, fruits and seeds of Chestnut as Guard against *E. p.*, 565. Prohibition Measures in Italy, 443.
Ephestia cautella: On Cotton in Brazil, 1306.
Epimys rufescens: On Coconut in Goa (Portuguese India), 878.
Epitetranychus althaeae: On Soya in Baden (Germany), 1191.
Epithrix: *E. atropae* and *E. pubescens* on Belladonna in Crimea, 784. *E. cucumeris*: Prohibitive Measures concerning importation of Potato Tubers etc. into Italy, 443.
Ergot (*Claviceps* sp.): On Cereals in Australia, 960.
Eriosoma (*Schizoneura*) *lanigera*: *Aphelinus mali*, Parasitic in Uruguay, 692.
Erodium cicutarium and *E. moschatum*: *Eutettix tenella* in Idaho and California 588.
Erynnia nitida: On *Galerucella luteola* in Italy, 582.
Erysiphe: *E. graminis*: Norwegian Wheat very susceptible to attack, 711. *E. Polygoni*, on Soya Bean in Baden (Germany), 1191.
Ethmia bittenella and *E. delliella* in Texas, 870.
Eucarazzia: *E. calthae* and *E. najadum* (= *Rhopalosiphum calthae* and *Rh. najadum*), 347. *E. picta* on Calamint in Italy, 347.
Euchlaena luxurians: *Sclerospora philippinensis* in the Philippines, 686.
Eucosma discretivana and *E. helianthana* in Texas, 870.
Euonymus: *E. europaeus*: *Aphis rumicis*, 964. *E. japonicus*: *Ceroplastes sinensis*, 465.
Euphorbia: Uredinae in Morocco, 862.
Euphorbia Esula see *Tithymalus Esula*.
Euproctis chrysorrhoea: Control methods in Orléanais (France), during 1920, 694.
Eutermes morio: On Coconut, in Porto Rico, 1307.
Eutettix tenella: On Sugar Beet in Idaho and California, 588.
Euthyrrhinus meditabundus: On Mango in Australia, 970.
Exenterus diprioni: On *Neodiprion lecontei* in U. S. A., 786.
Exoascus deformans: Resistant Peach Vars. in Italy, 229.
Exochomus sp.: Nat. Enemy of *Ceroplastes sinensis*, 465.

FAGOPYRUM FAGOPYRUM: *Pyrausta ainslei* reared on the Leaves in U. S. A., 783.
Fearn's Pippin, Apple Var. Immune to Spotting, 108.
Federated Malay States: Diseases and Pests of Camphor, 951.
Fennel: Injurious Hymenoptera, Diptera and Coleoptera and *Graphosoma lineatum* in Crimea, 784.
Festuca arundinacea, *F. elatior*, *F. Hookeriana*: *Claviceps* sp. in Australia, 960.
Field Mouse, Red (*Hypodeus glareolus*), 1193.
Fig: *Lonchaea aristella* in France, 1077.
Firs, White: *Hypodeus glareolus* in Switzerland, 699. Douglas Fir, see *Pseudotsuga Douglasii*.
Flag Smut (*Urocystis Tritici*): On wheat, 865.
Flame-throwers: In Control of Moroccan Cricket in Crau, 112.
Flax: *Asterocystis radicis* and *Melampsora Lini* in Morocco, 862. *Melampsora Lini* in India, 446.
Flies, Fruit: Introduced into Egypt, 581. Prohibitive Measures for importation of Fresh Fruits into Italy, 443. See also Spanish Fly, White Fly.

Florida: *Bacterium Solanacearum* on Castor Plant, 1062. *Gracilaria perseae* on Avocado, 240. *Peronospora Hyoscyami* on Tobacco, 687. *Puccinia Arachidis* on Peanut, 449. Rice Weevil (*Sitophilus oryza*), 463.

Fomes: *F. annosus* on Weymouth Pine in Switzerland, 1193. *F. fulvus* on Almond in Italy, 577.

Foodstuffs: *Sitophilus oryza* in U. S. A., 463.

Foot-Rot: Of Tomato (*Phytophthora cryptogea, Phyt. parasitica,* and *Rhizoctonia Solani*), 1296. Of Wheat (*Ophiobolus graminis*) in N. Y. State, 104. See also Straw-Blight.

Formaldehyde: Injuries to Wheat Seed resulting from Drying after Disinfection with Formaldehyde, 573.

France: Bacteria, Anaerobic, and Gummosis of Walnut, 343. Bacteriosis of Ivy, 457. *Ceroplastes sinensis*, on Citrus trees and other Cultivated Plants, 465. *Colletotrichum Agaves* on *Agave* spp., 1061. *Dociostaurus maroccanus* (Moroccan Cricket), Control measures in Crau, 112. *Endothia parasitica*, Prohibitive Measures concerning Importation of Plants, Fruits and Seeds of Chestnut, 565. *Euproctis chrysorrhoea*; on Fruit and Forest trees in Orléanais, Control Measures, 694. *Hoplisus laticinctus*, on *Begonia tuberosa*, 237. *Hybernia defoliaria* on Fruit Trees, Control with Tanglefoot, 584. *Laspeyresia conicolana*, on *Pinus Laricio* var. *tenuifolia*, 467. *Lonchaea aristella* on Fig. 1077. *Operophthera* (*Cheimatobia*) *brumata* on Fruit Trees, Control with Tanglefoot, 584. *Otiorrhynchus sulcatus*, on *Begonia tuberosa*, 237. *Pseudococcus*; Introduction of Nat. Enemy *Cryptolaemus montrouzieri* into S. France, 1074. *Spirospora Castaneae*, on Chestnuts, 109. Walnut Parasites, 1123.

Fruits: *Brachypternus aurantius* in India, 583. *Sitophilus oryza* in U. S. A., 463. Fresh Fruits: Prohibitive Measures concerning importation into Italy to guard against *Aonidiella perniciosa, Laspeyresia molesta* and Fruit Flies, 443.

Fruit Trees: *Aleurocanthus woglumi* in Cuba, 955. Deterioration of trees caused by Bud Variations, 148. Control Methods: For *Euproctis chrysorrhoea* in France, 694. For *Lytta vesicatoria* in Italy, 967. For *Operophthera* (*Cheimatobia*) *brumata* and *Hybernia defoliaria* in France by use of "Tanglefoot", 584. For Rejuvenation, Treatment, 958.

Fuchsia: *Bacterium Solanacearum*. 1062.

Fulcaster and Fultz: Wheat Vars. Resistant to *Urocystis Tritici* in U. S. A., 865.

Fumagine, 1074.

Fumago sp.: On *Melaleuca Leucadendron* var. *viridifolia* in New-Caledonia, 1063.

Fumigation: Use of Rubber Sheets for f. with Hydrocyanic Acid, 872.

Fungicides: See Copper Compounds and Zinc Compounds.

"Fusagare" (*Physalospora baccae*), 1299.

Fusarium: *F. conglutinans*: Resistance to Different Cabbage vars. in U. S. A., 338. *F. cubense*. On Banana in the Philippines, 459. *F. Lycopersici*: On Tomato in Victoria (Australia), 107. *F. roseum*: On Wheat in Rice Fields of Italy, 959. *Fusarium* sp. Cause of Banana Panama Disease in Cuba, 955.

GALANTHUS spp.: *Botrytis galanthina* in England, 456
Galerucella: *G. luteola*; *Degeeria collaris* in Italy, 582. *G. nymphaeae* on *Nymphaea advena* (= *Nuphar advena*) in New Jersey, 238.
Ganoderma applanatum: On Oil Palm (*Elaeis guineensis*) in São Thomé, 232.
Gardenia florida: *Ceroplastes sinensis*, 465.
Gases: Toxication of Certain Gases on Insects, Seeds and Fungi, 462. Toxic Action of Illuminating Gas, 462.
Gasterocercodes gossypii: On Cotton in Brazil, 1306.
Gelechia: *G. bosquella*, *G. hibiscella*, *G. neotrophella* in Texas, 870 *G. gossypiella*, See *Pectinophora gossypiella* and *Platyedra gossypiella*.
Georgia: *Bacterium Solanacearum* on Castor Plant, 1062. Mosaic of Maize, 99 *Peronospora Hyoscyami* on Tobacco, 687
Geranium. *Rhizobius lophantae* in Italy, 580.
Germany: *Phthorimaea* (*Lita*) *ocellatella* on Beet, 1308. Pests of Soya Bean in Baden, 1191.
Giant Moth Borer, of Sugar Cane (*Castnia licus*), 1183.
Gibberella Saubinetii, 959.
Gladiolus spp.: *Bacterium marginatum* in District of Columbia and in Illinois, 1065.
Gloeosporium: *G. Agaves*: On *Agave* sp. in Brazil, 1061. *G. Bombacis* on *Bombax insigne* in Brazil, 576 *G. caulivorum* on Wild Clover in Morocco, 862 *Gloeosporium* sp. Conidial Form of *Physalospora Miyabeana* on *Salix purpurea* var. *angustifolia*, in Japan, 1180.
Gloria Mundi, Apple Var. Immune to Spotting, 108.
"Glory of Enkhuizen": Cabbage Var. resistant to *Fusarium conglutinans* in U. S. A., 338.
Glyphodes pyloalis in Texas, 707.
Gnomonia Juglandis, 101.
Goa (Portuguese India): *Epimys rufescens* and *Nesokia bengalensis* (?) on Coconut and Cereals respectively, 878. *Oryctes rhinoceros* and *Rhynchophorus ferrugineus* on Coconut, 969. *Prodenia litura* and *Spodoptera mauritia* on Rice, 874
Golden-backed Woodpecker (*Brachypternus aurantius*), 583.
"Golden Bantam" Maize var. immune to Mosaic in Louisiana, 99.
Gombo (*Hibiscus esculentus*): *Earias insulana* var *anthophilana* in Cyrenaica, 353
"Gorgojo barreno del tallo" (*Metamasius hemipterus*), 1307
Gorgophia sp.: On Cotton in Brazil, 1306
Gossyparia ulmi, 233.
Gossypium barbadense: *Earias insulana* var *anthophilana* in Cyrenaica, 353. *Ovulariopsis Gossypii*, in Barbados, 231.
Gracilaria perseae: On Avocado (*Persea gratissima*) in Florida, 240.
Graminae: *Claviceps* sp in Australia, 960. *Sesamia nonagrioides*, 158
Grapes, See Vines
Graphosoma lineatum: On Fennel in Crimea, 784.
Grasshoppers: See Locusts.
Great Britain: England, Bacteriosis; On *Richardia*, 575. *Botrytis galanthina*: On *Galanthus* spp., 756. *Botrytis Douglasii*, On Larch, 346. On *Pinus sylvestris*, 346. *Phomopsis Pseudotsugae*, 345. *Phytophthora cryptogea*, *Phyt parasitica*: On Tomato, 1296. *Rhizoctonia Solani*: On Tomato, 1296. Spotting: of Apples, 107.
Scotland: *Botrytis Douglasii*: On *Pseudotsuga Douglasii*, 346.

Hypoderma pinicola and *H. strobilicola* on *Pinus sylvestris* and *P. Strobus* var. *nana* respectively, 234. *Phomopsis Pseudotsugae*: On *Ps. Douglasii*, 110. Diseases of *Ps. Douglasii*, 1300.

General: *Anthonomus cinctus* and *A. pomorum*: On Apples, 1192. *Chermes cooleyi*: On *Pseudotsuga Douglasii*, 346. Imperial Bureau of Entomology and Imperial B. of Mycology, 566.

Greece: *Micrococcus* (*Staphylococcus*) *acridicida* attacking Grasshopper, 1184.

Gryllotalpa sp.: Destroyed by *Athene brama* in India, 111.

" Guastaticcio ", 230.

Guava: *Ceratitis capitata* in Egypt, 581.

Guignardia: *G. baccae*, 1299. *G. Bidwelli*, see Blackrot of Grapes.

Gumming: Of Sugar Cane in Porto Rico (*Bacterium vascularum*), 105. Of Walnut in France, 343.

" Gusana blanco " (*Phyllophaga portoricensis*), 1307.

Guiana, British: Injurious Insects to Cultivated Plants, 1183.

" Gypsy " Wheat Var. Resistant to *Urocystis Tritici* in U. S. A., 865.

Gyropsylla ilicicola: On Maté in Argentina, 1309.

HAIRY VETCH: Diseases and Pests in U. S. A., 48.

Hawai: *Opius fletcheri* on *Bactrocera cucurbitae* and *Ceratitis capitata*, 349. *Stenommatus musae* on Banana, 348.

Heliothis: *H. obsoleta*: Control Methods in Cambodia, 1221. *H. peltigera*: On Belladonna in Crimea, 784. *H.* (*Chloridea*) *obsoleta* and *H.* (*Chlor.*) *virescens* in Texas, 870.

Helminthosporium gramineum: On Wheat in Emilia (Italy), 1295. Resistant Barley vars. in Sweden, 144.

Hemerocampa pseudotsugata: On *Pseudotsuga Douglasii* in Brit. Columbia (Canada), 590. *H. vetusta gulosa*, 590.

Hemichionaspis: *H. aspidistrae*: Host of *Aphelinus mytilaspidis* in Japan, 1185. *H. minor* on Cotton in Brazil, 1306.

Henbane, Common (*Psyllioides hyoscyami*): In Crimea, 784.

Heterodera: *H. radicicola*: *Althaea officinalis* in Italy, 452. Resistant Vars. of *Vigna sinensis* in U. S. A., 144. *H. schachtii*: Resistant Barley vars. in Sweden, 144.

Heterosporium gracile: On *Iris pallida* in Italy, 452.

Hevea: Alternate Tapping to Prevent Brown Bast etc., 54.

Hibiscus: *H. cannabinus*, 1058. *H. cannabinus*: *Dysdercus cingulatus* in India, 446. *H. Sabdariffa*, 446, 1057. *H. esculentus*, 353, 870. *H. esculentus*: *Earias insulana* var. *anthophilana* in Cyrenaica, 353. *H. lasiocarpus*, 870.

Holcocera confamulella and *H. ochrocephala* in Texas, 870.

Hollyhock: *Apion longirostre*, *A. validum*, *Baris nitens* and *Podagrica malvae* in Crimea, 784.

Homoeosoma electellum: In Texas, 870.

Hoplisus laticinctus: On *Begonia tuberosa*, in France, 237.

Hoplocerambyx spinicornis: Destroyed by *Brachypternus aurantius* in India, 583.

Hordeum distichon and *H. tetrastichum*: *Puccinia graminis* and *P. glumarum* in Morocco, 862.

Hybernia defoliaria: Control Measures by use of Tanglefoot in France, 584.

Hybridisation: Resistance of Certain Trees to Diseases and Pests, 40.

Hylobius abietis: On Weymouth Pine in Switzerland, 1193.

Hymenoptera: Parasitic on Coccids in Japan, 1185. Parasitic on *Diatraea saccharalis* in Brit. Guiana, 1183.

Hyoscyamus: *H. albus* and *H. niger*: *Macrosporium Solani* in Italy, 452. *H. niger*: *Peronospora Hyoscyami*, 687.

Hypertrophy: Of Spruces; Chemical Analysis of Soil, 797.

Hyphaene thebaica: *Coccotrypes dactyliperda*, 580.

Hypoderma pinicola: On *Pinus sylvestris*; *H. strobilicola* on *P. Strobus* var. *nana*, in Scotland, 234.

Hypodeus glareolus: On Weymouth Pine in Switzerland, 1193. On White Fir in Switzerland, 699.

ICERYA PURCHASI: Attacked by *Novius cardinalis* in the Oasis, Tripoli, 461. On Single Specimen of Hybrid Rose de l'Hay in Italy, 452.

Ichneumonides: On *Acanthopsyche junodi* in Natal, 1186.

Idaho (U. S.): *Eutettix tenella* on Sugar Beet, 588.

Ilex paraguariensis: *Gyropsylla ilicicola* in Argentina, 1309.

"Illini Chief": Wheat Var. Susceptible to *Urocystis Tritici* in U. S. A., 865.

Illinois: *Bacterium marginatum* on *Gladiolus* spp., 1066.

Impatiens Balsamina: *Bacterium Solanacearum*, 1062.

Imperial Bureau of Entomology and Imperial Bureau of Mycology, 566.

India: *Athene brama*, Useful Bird, 111. *Brachypternus aurantius*, Useful Bird, 583. *Calandra glandium*, reared from Acorns of *Quercus dilatata* and *Q. incana*, 348. *Cal. shoreae*: On Seeds of *Shorea robusta* and *Dipterocarpus turbinatus*, 348. *Colletotrichum Agaves*: On *Agave rigida* (Sisal), 1061. *Coptotermes heimi* On *Dalbergia Sissoo*, 583. *Dicrurus macrocercus*, Useful Bird, 966. *Hoplocerambyx spinicornis*, on *Shorea robusta* in E. Bengal, 583. Mite, Undetermined, on Potato, 696. On *Cyamopsis psoraloides* (identical to that found on Potato), 696. *Oryctes rhinoceros* and *Rhynchophorus ferrugineus*: On Palms in Madras, 583. *Ustilago Crameri* on *Setaria italica* in Madras, 775. Wilt Disease, of *Indigofera arrecta*, 446, 1057. General: — Diseases and Pests; of Citrus Fruits, 1101; of Dates, 507; of *Hibiscus cannabinus*, Flax, *Indigofera*, Sugar Cane and Wheat, 446.

Indian Meal Moth (*Plodia interpunctella*), 689.

Indigofera arrecta: Wilt Disease in India, 446, 1057.

Indo-China: *Colletotrichum Agaves*, on Sisal (*Agave rigida*), 1061.

Insectarium, Forest: In Spain, 1301.

Institutes: For Protection of Agriculture, in Brazil, 442.

Iris: *I. florentina*, *I. germanica*: *Septoria Iridis* in Latium (Italy), 455. *I. pallida*: *Heterosporium gracile*, in Italy, 452.

Irish Potato Blight (*Phytophthora infestans*): On Tomato in Victoria (Australia), 107.

Isaniris ater: On Citrus Fruits and Trees of Gen. *Brachystegia* etc. in S. Rhodesia and in Nyasaland, 348.

Isaria Psychidae: On *Acanthopsyche junodi* in Natal, 1186.

Isophrictis similiella, in Texas, 870.

Italy: "Anthracnose": Nosiola Trentino Grape, resistant, 728. Aphids, 347. "Arrabbiaticcio" ("Terregatée"): Researches, 230. *Attacus cynthia*: On Cherry Pear, Plum and Plane Trees, 1071. *Ce-*

roplastes sinensis, on Citrus Fruits, 465. Coleoptera, Foreign observed in Latium, 580. *Degeeria collaris* and *Erynnia nitida*, Parasites of *Galerucella luteola*, 582. *Exoascus deformans*, Resistant Peach, Vars , 229. *Fomes fulvus*: On Almond, 577. *Fusarium roseum*: on Wheat, 959. *Helminthosporium gramineum* on Wheat in Emilia, 1295. Lodging: "Cignarellone" Wheat Var. of Molise, resistant, 283. Comparative Resistance of Selected Todaro Wheats in Molise, 718. *Lytta vesicatoria*: Control of attack on Fruit Trees, 967. "Mal Nero" ("Nerume") on Walnut in the Campania, 679. Mildew: Resistance of "Sirah" Grape, 512. Oidium: Oak, 568. Resistance of Sirah Grape, 512. *Phoma Ferrarisii*, Cause of Tomato Rot in in Piedmont, 1065. *Pleospora infectoria* var. *aucubicola*: On *Aucuba japonica*, 688. Phylloxera: Resistance of Pyrovano Hybrids, 1127. *Ramularia* sp. on Tomatoes in Piedmont, 1065. Rust: Resistance of "Cignarellone" Wheat Var. in Molise, 283. Comparative Resistance of selected Todaro Wheats in Molise, 718. "Scald": of Citrus Fruits in S. Italy, 860. *Septoria Iridis*: On Iris, in the Latium, 455. *Silvestrina silvestrii* var. *cecconiana*: On Olives 239. Smut: On Tomato in Piedmont, 1065. Resistance of "Noe" Wheats, 810. *Trichothecium roseum*: On Apples and Pears, 779. General: Pests of Artichokes, in Roman Maremma, 60. Plant and Animal Parasites of Medicinal and Essential Oil Plants, 452. Pests and Diseases of Vines: Comparative Resistance of Trentino Vars. "Negrara" and "Teroldigo," 302. Decrees, Regulating importation of Plants, 96, 443. Phytopathological Service Organisation and Working of, 678.

Ivy: Bacteriosis observed in France, 457. *Rhizobius lophantae* in Italy, 580.

JAPAN: Chalcididae Parasites on Coccids, 1185. *Physalospora baccae* on Vine, 1299. *Ph. Miyabeana* and Conidial Form (*Gloeosporium*) and *Marssonina* sp. on *Salix purpurea* var. *augustifolia*, 1180. *Pseudomonas Pruni* on Plum, Peach and other Rosaceae, 1297.

"Jones Winter Fife": Wheat Var. Susceptible to *Urocystis Tritici* in U. S. A., 865.

"KAVANGIRE": Sugar Cane Var. Resistant to Poot Disease 710.

Kentia spp.: *Chrysomphalus dictyospermi* in California, 689.

Kentucky: *Sclerospora macrospora* on *Bromus commutatus* and on wheat, 1059.

"King Crow" (*Dicrurus macrocercus*), 966.

"Kiskadee" (*Pitangus sulphuratus*), 1183.

"LAGARTA ROSEA,, (*Platyedra gossypiella*): of Cotton, 1306.

Lagorotis diprioni and *L. virginiana*: on *Neodiprion lecontei* in U. S. A., 786.

"Lane's Prince Albert": Apple Var. liable to Spotting in England, 108.

Laphygma frugiperda: On Sugar Cane in Brit, Guiana, 1183.

Larch: *Botrytis Douglasii* in England, 346.

Larix: *L. americana*: *Neodiprion lecontei* in U. S. A., 486. *L. occidentalis*: *Thelephora caryophyllea*: *Th. terrestris* in U. S. A., 869.

Lasioderma serricorne: In Dried Co-

prah and Coprah Cakes in California, 689.
Lasius fuliginosus, *L. marginatus*, 232.
Laspeyresia: *L.* (*Grapholitha*) *conicolana*, on *Pinus Laricio* var. *tenuifolia* in France, 467. *L. molesta*, See "Tignola orientale del pesco". *L. nigricana*: *L. novimundi* on Peas and Field Peas in Wisconsin, 464. *L. tristrigana* in Texas, 870.
Late Flat Dutch: Cabbage Var. Resistant to *Fusarium conglutinans* in U. S. A., 338.
Leaf Spot: Of Paw-paw (*Phyllosticta Caricae-Papayae*, 1064; Of Pea-nut (*Septogloeum Arachidis*), 342; Of Tomato (*Septoria Lycopersici*), 1179.
Leafy Spurge (*Tithymalus Esula* = *Euphorbia Esula*), 1070.
Lema bilineata: On Tobacco in S. Africa, 354.
Lepidosaphes gloveri (Citrus Scale): Prohibitive Measures concerning importation into Italy, 443.
Leptosphaeria vagabunda: On "Spotted" Apples in England, 108.
Lettuce: *Sclerotinia minor* in U. S. A., 574.
Leucotermes lucifugus: Destroyed by Chloropicrin, 114.
"Lithiase", of Pears, in S. Africa, 957.
Locust: Grasshoppers. Attacked by *Micrococcus* (*Staphylococcus*) *acridicida* in Greece, 1184. International Convention for Control of L. in Rome, October 31, 1920, 221. Invasion of L. in Brit. Guiana, 1183. Industrial Utilisation, 18. See also Cricket.
Locusta viridissima: Inoculation tests with *Micrococcus* (*Staphylococcus*) *acridicida* in Belgium, 1184.
Lodging: Resistant Wheat Vars.; "Cignarellone" in Molise (Italy), 283. "Mogarbia" in Cyrenaica, 282. Behaviour of Selected Todaro Vars. Molise (Italy), 718.
Lolium: *L. multiflorum* var., *L. perenne* and *L. temulentum*: *Claviceps* sp. in Australia, 960.
Lonchaea aristella: On Figs in France, 1077.
Lotus: (*Nelumbium speciosum*): *Alternaria Nelumbii*, 778.
Lophyrus pini (*L. similis*): On Weymouth Pine in Switzerland, 1193.
Louisiana: Mosaic of Maize, 99.
Lucerne: *Anuraphis fasciatus* in Italy, 347. *Cuscuta racemosa* in Rio-Negro (Argentina), 1069. Impurities, Seed, in New South Wales, 493. Resistance to Cold and Rust at Mahndorf (Germany), 478. *Tipula quaylii* and *T. simplex* in California, 873.
Lupins: *Uromyces Anthyllidis* in Morocco, 862.
Lygus pratensis: On Soya Bean in Baden (Germany), 1191.
Lytta vesicatoria: Control in Italy, 967.

MACROPHOMA RENIFORMIS: Cause of Black Rot of Grapes in the Caucasus, 1299.
Macrosporium: *M. Cavarae* on *Ricinus communis*; *M. Papaveris* on *Papaver somniferum*; *M. Solani* on *Atropa Belladonna*, *Datura fastuosa*, *D. Metel*, *D. Stramonium*, *Hyoscyamus albus*, and *H. niger* in Italy, 452.
Madras (Pres.): *Oryctes rhinoceros*, and *Rhynchophorus ferrugineus*, 583. *Ustilago Crameri* on *Setaria italica*, 775.
Maize: *Ceroplastes sinensis*, 465. "Mosaic" in Porto Rico, Louisiana and Georgia, 99. *Puccinia Maydis* in Morocco, 862. *Pyrausta nubilalis* in Canada, 585. *Sclerospora philippinensis*, in the Philippines, 686. *Systates exaptus*, *Tanymecus*

agricola and *T. destructor* in S. Rhodesia, 348. *Ustilago Maydis* in Morocco, 862.

"Mal Nero", of Walnut in the Campania (Italy), 679.

Malvaceae: *Puccinia Malvacearum* in Morocco, 862.

Mamestra brassicae: On Belladonna in Crimea, 784.

Mandarin: *Ceroplastes sinensis*, 465.

Mango: *Chaetodacus zonatus*, collected from Fruit confiscated at Port Said, 581. *Euthyrrhinus meditabundus*, Host of *Chalcis euthyrrhini* in N. Queensland, 965. *E. m.* and *Mastotermes darwiniensis* in Australia, 970.

"Marciume amaro" (Bitter Rot) or Marciume del cuore (Core Rot) *Trichothecium roseum*: In Apples and Pears.

Marsh Mallow: *Podagrica malvae* and *Oxythyrea funesta* in Crimea, 784.

Marssonia Juglandis: Over-wintering on the Branches and Shoots of Walnut, 101.

Marssonina sp.: On *Salix purpurea angustifolia* in Japan, 1180.

"Maryland Flat Dutch", Var. of Cabbage resistant to *Fusarium conglutinans* in U. S. A., 338.

Massachusetts: *Stilpnotia salicis* on Poplars and Willows, 877.

Mastotermes darwiniensis: On Mango in Australia, 970.

Maté: *Gyropsylla ilicicola* in Argentina, 1309.

"Matizado" of Sugar Cane, 955.

Mauritius: *Calandra shoreae* on Seeds of *Shorea robusta* and *Dipterocarpus turbinatus*, 348.

Mediterranean Fruit Fly (*Ceratitis capitata*), 349.

Melaleuca Leucadendron var. *viridiflora*: *Fumago* sp. in New Caledonia, 1063.

Melampsora Lini: On Flax in Morocco, 862. In India, 446.

Melanconia (*Marssonia*) *Juglandis*. Overwintering. On branches and Schools of Walnut, 101.

Melanospora, 768. *M. parasitica* on *Isaria Psychidae* injurious to *Acanthopsyche junodi* in Natal, 486.

Melissa officinalis: *Pleospora Melissae* in Italy, 452.

Melolontha vulgaris: On Soya Bean in Baden Germany), 119

Melon Fly (*Bactrocera cucurbitae*), 349.

Meskea dyspteraria, in Texas, 870.

Metamasius hemipterus: On Sugar Cane in Brit. Guiana, 1183. On Coconut in Porto Rico, 307.

Mexican Bean Weevil (*Spermophagus pectoralis*), 689.

Mexico: *Phloeosinus* sp., on Cypres, 698.

Michigan: *Pseudomonas Apii* on Celery, 868.

Microbracon sp.: Parasite of *Pyrausta ainsliei*, in U. S. A., 783.

Micrococcus (*Staphylococcus*) *acridicida*: Attack on Locusts in Greece, 1184.

Microsphaera Alni, *Micr. quercina*, 568.

Mildew: Of Cereals (*Sclerospora macrospora*) in Tennessee and in Kentucky, 1059. Of Potatoes, Effect of Copper Compounds, 340. Resistance of Aerial Tubers, 142. Of Vines, Acid Reaction of Leaves covered with Mildew, after Treatment with Bordeaux Mixture, 1058. Effect of Copper Compounds, 340. "Couderc" Direct Hybrid Producter, Resistant, 165. "Sirah" Grape, Resistant, in Italy, 512.

Mineola indiginella: On *Cotoneaster* spp. in New Jersey, 875.

Mysepyris grandiceps: on Larvae of *Xylotrechus quadripes* in Tonkin, 1075.

Mite, Undetermined: On Potato in India, 696.

Mogarbia: Wheat Var. in Cyrenaica

Resistant to Rust and Lodging, 283.
Molise (Italy): Cignarellone, Wheat Var. resistant to Rust and Lodging, 283.
Montserrat: *Pectinophora* (*Gelechia*) *gossypiella* on Cotton, 587.
Moodna ostrinella: in Texas, 870.
Morocco: Diseases and Pests, 862.
Morus alba: *Silvestrina silvestrii* in Capetown and São Paolo 239.
Mosaic: Maize, in Porto Rico, Louisiana and Georgia, 99. Sugar Cane: In Cuba, 955.
Muehlenbeckia platyclados: *Ceroplastes sinensis*, 465.
Muridae: Feeding on *Acanthopsyche junodi* in Natal, 1186.
Musa: *M. sapientum*, var. Latundan *Fusarium cubense*; *M. textilis* Resistant to *F. c.* in the Philippines, 459.
"Muscardine" (*Botrytis Bassiana*), 844.
Mycogone, 109.
Myelophilus (*Hylesinus*) *minor* and *M. piniperda*; on Weymouth Pine in Switzerland, 1193.
Myrmicaria eumenoides: Nat. Enemy of *Lema bilineata* in S. Africa, 354.

NATAL: *Acanthopsyche junodi*, on *Acacia mollissima*, Nat. Enemies of 1186. *Phyllosticta Caricae-Papayae* on Paw-paw, 1064. *Silvestrina silvestrii* in Fruits of *Olea verrucosa*, 239.
Necrobia rufipes: In Dried Coprah and Coprah Products in California, 689.
"Negrara", Behaviour of this Vine to Diseases and Pests in Trentino (Italy), 302.
Nelumbium: *N. luteum*: *Pyrausta penitalis*, 783. *N. speciosum*: *Alternaria Nelumbii* in U. S. A., 778.
Neodiprion lecontei: On Pines and *Larix americana* in U. S. A., 786.
Neopales maera: On *Neodiprion lecontei* in U. S. A., 786.
Nerume ("Mal Nero"): Of Walnut, in Campania (Italy), 679.
Nesokia bengalensis (?): On Cereals in Goa (Portuguese India), 878.
New Caledonia: *Fumago* sp. on *Melaleuca Leucadendron* var. *viridiflora*, 1063.
New Hampshire: *Stilpnotia salicis* on Poplars and Willows, 877.
New Jersey: *Galerucella nymphaeae* on *Nymphaea* (*Nuphar*) *advena*, 238. *Mineola indiginella* on *Cotoneaster* spp., 875.
New South Wales: *Phytophthora* sp. and *Septoria Lycopersici* on Tomato, 1179. *Pulvinaria ornata* on Citron and on *Pittosporum undulatum*, 968. Lucerne Seed Impurities, 493.
"Newton Wonder": Apple Var. Liable to Spotting in England, 108.
New York (State of): *Ceutorrhynchus quadridens* (Cabbage Seed Stalk Weevil) in Long Island, 1310.
New Zealand: *Pemphigus populi-transversus* on Poplars and Crucifereae, 241.
Niaouli, 1063.
Nicandra physaloides: *Lema bilineata* in S. Africa, 354.
Nicotiana glauca: *Peronospora Hyoscyami* in California, 687.
Nightjar: Nat. Enemy of *Oncopera mitocera* in Queensland, 1190.
Noctuella rufofascialis: In Texas, 870.
Norway: Wheat with Light Ears very susceptible to *Erysiphe graminis* and to *Tilletia Caries*, 711.
"Nosiola": Trentino Vine Resistant to Anthracnose, 728.
Novius cardinalis: Nat. Enemy of *Icerya purchasi* in Oasis of Tripoli, 461.
Nuphar advena (= *Nymphaea advena*); *Galerucella nymphaeae* in New Jersey, 238.
Nyasaland: *Isaniris ater* on Citrus Fruits, 348.
Nymphaea advena (= *Nuphar advena*): *Galerucella nymphaeae* in New Jersey, 238.

OAK : Observations on the Perfect Form of Oidium, in Italy, 568.

Oats : "Record" Var. Resistant to Rust in Italy, 1111. Rust Resistance in U. S. A., 376.

Oceania : Curculionidae on Cultivated Plants, 348.

Oedematophorus venapunctus : In Texas 870.

Oidium : *O. alphitoides* ; *O. gemmiparum, O. quercinum, O. q.* var. *gemmiparum,* 568. *O. Tuckeri* on Vine in Morocco, 862.

Oidium : Oak, Observations on Perfect Form of Oak O. in Italy, 568. Vine : Sirah Var. Resistant in Italy, 512.

Oil Palm (*Elaeis guineensis*) : *Ganoderma applanatum* in S. Thomé, 232.

Old Witch (*Crotophaga ani*), 1183.

Olea : *O. europaea* : *Silvestrina silvestrii* var. *cecconiana,* in Italy, 239. *O verrucosa* : *Silvestrina silvestrii* in Natal, 239.

Olives : Bacterial Diseases in Morocco, 862. *Dacus oleae* on Fruit sent from Cyprus to Alexandria, 581. *Silvestrina silvestrii* var. *cecconiana,* in Italy, 239. *Tetranema agnesii* in Italy, 347. Rejuvenation Treatment for, 958.

Oncopeltus sp. : On Cotton in Brazil, 1306.

Oncopera mitocera : On Pasture Land in Queensland, 1190.

Onion : Smut (*Urocystis Cepulae*), in England, 454.

Oniscus spp. : On Soya Bean in Baden (Germany), 1191.

Operophthera (*Cheimatobia*) *brumata* : Control Measures by Use of "Tanglefoot" in France, 584.

Ophiobolus : *O. graminis* on Wheat in Washington State, 104. *O. graminis* and *O. herpotrichus* in Italy, 230.

Opius fletcheri : On *Bactrocera cucurbitae* in Hawai, 349.

Opuntia : *Carpophilus dimidiatus* in California, 689. Fibre utilised for Sheets in Fumigation of Trees with Hydrocyanic Acid, 872.

Orange : *Ceratitis capitata,* in Egypt, 581. *Ceroplastes sinensis,* 465. Effect of Sprays on Composition, 609.

Oryctes rhinoceros : On Coconut in Goa (Portuguese India), 969. On Palms in Madras, and Destroyed by *Brachypternus aurantius,* 583.

"Otaheite" : Sugar Cane Var. Subject to Gumming (*Bacterium vascularum*) in Porto Rico, 105.

Otiorrhynchus sulcatus : On *Begonia tuberosa* in France, 237.

Ovulariopsis : *O. Gossypii* : On *Gossypium barbadense,* and *O. obclavata* on *Tecoma leucoxylon* in Barbados, 231.

Oxalis cernua and *Oxalis* sp., Uredinae (conidial form of *Puccinia Maydis*) in Morocco, 862.

Oxythyrea funesta : On Marsh Mallow in Crimea, 784.

PACHYZANCLA BIPUNCTALIS : In Texas, 870.

Palaeornis torquata, 111.

Palms : *Oryctes rhinoceros* and *Rhynchophorus ferrugineus* in Madras, 583. See also Oil Palm.

Pandemis pyrusana : In California, 697.

Panicum bulbosum : *Claviceps* sp. in Australia, 960.

Pantomorus (*Aramigus*) *fulleri* : In Latium (Italy), 580.

(*Panzeria*) *Pyraustomyia penitalis* : On *Pyrausta ainsliei* in U. S. A., 783.

Papaver : *P. Rhoeas* on Wheat ; Control with Copper Sulphate, 963. *P. somniferum* : *Macrosporium Papaveris* in Italy, 452.

Paraglypta tubigera : On Larvae of *Xylotrechus quadripes* in Tonkin, 1075.

Parana : Fungous Diseases of Wheat, 285.

" Parana " (Grass) : " Salivita " Pest in Cuba, 955.

Paris Green, 693.

Pastures: *Oncopera mitocera* in Queensland, 1190. *Pentaphis apuliae* and *Tetraneura reticulata* in Italy, 347. *Tipula quaylii* and *T. simplex* in California, 875.

Paw-paw : *Phyllosticta Caricae-Papayae* in Natal, 1064.

" Pax " Sprayer, 670.

Peach : *Ceratitis capitata* in Egypt, 581. *Exoascus deformans*. Resistance of Certain Vars. in Italy, 229. Rejuvenation Treatment for *E. d.*, 958. *Penicillium italicum* and *Rhizopus nigricans* in S. Africa, 957. *Pseudomonas Pruni* in Japan, 1297.

Peach leaf Curl (*Exoascus deformans*), 229, 958.

Peanut : *Carpophilus dimidiatus*, *Plodia interpunctella*, *Silvanus surinamensis*, *Tenebroides mauritanicus*, *Tribolium castaneum* in California, 689. *Puccinia Arachidis* in Florida, 444. *Septogloeum Arachidis* in S. Africa, 342.

Pears : *Attacus cynthia*, 1071. Lithiase in S. Africa, 957. *Trichothecium roseum* in Italy, 779.

Peas : *Laspeyresia novimundi* in Wisconsin, 464. *Uromyces Pisi* in Morocco, 862.

" Peasgood Nonsuch ", Apple Var. Liable to Spotting in England, 108.

Pectinophora gossypiella : Effect on Cotton Oil Percentage, 671. On Cotton in Montserrat and St. Kitts (W. Indies), 587. Lepidoptera in Texas which may be confused with *P. g.*, 870.

Pediculoides ventricosus : Feeding on *Sitophilus linearis* in U. S. A., 355. On *Sitophilus oryza* in U. S. A., 463.

Peduncle Rot, of Vine, 1299.

Pemphigus populi-transversus : On Poplars and Cruciferae in New Zealand, 241.

Penicillium : *P. italicum* on Peaches and Plums in S. Africa, 957. On Caryopses of Barley and Wheat, 863.

Pennsylvania : *Phytophthora* sp. on Peonies, 1067. *Synchytrium endobioticum* on Tomato, 453.

Pentaphis apuliae in Meadows and *P. viridescens* on Couchgrass in Italy, 347.

Peonies : *Phytophthora* sp. in Pennsylvania, 1067.

Perennial Sow Thistle (*Sonchus oleraceus*), 579.

" Perforador de la palma de coco " (*Platypus* sp.), 1307.

Peridermium Strobi : On *Pinus Strobus* in Switzerland, 1193.

Perilampus hyalinus : On *Neodiprion lecontei* in U. S. A., 786.

Perissopterus mexicanus : On *Aulacaspis pentagona* in Japan, 1185.

Peronea sp. : In California, 697.

Peronospora Hyoscyami : On Tobacco in Florida and Georgia, 687.

Persea gratissima : *Chrysomphalus dictyospermi* in California, 689. See Avocado.

Peru : Diseases and Pests of Vine, 1230.

Pestalozzia Hartigii : On Tea in Ceylon, 393.

Phalaris : *Ph. bulbosa*, Resistant to Disease in Argentina, 1215. *Ph. minor* : *Claviceps* sp. in Australia, 960.

Phalonia cephalanthana, in Texas, 570.

Pheidole punctulata : Nat. Enemy of *Lema bilineata* in S. Africa, 353.

Phenacoccus pergandei : *Coccophagus lecanii* in Japan, 1155.

Philadelphus coronarius : *Ceroplastes sinensis*, 465.

Philippines : *Anthonomus grandis*. Resistant Cotton Vars., 722. *Dryopeia hirsuta* on Rice, 695. *Fusarium cubense* on Banana, var. "Latundan", 459. Injurious Insects on Cultivated Plants, 1302. *Sclerospora philippinensis* on Maize etc., 686. *Sclerospora Sacchari*, on Sugar Cane, 1177. *Targionia merrilli* on *Rhizophora mucronata*, 117.

Philopsyche abdominalis: On *Acanthopsyche junodi* in Natal, 1186.

Phloeosinus sp.: On Cypress in Mexico, 698.

Phoenix dactylifera: *Coccotrypes dactyliperda*, 580.

Phoma: *Ph. citricarpa* on *Citrus nobilis* and *C. sinensis* in China, 780. *Ph. Ferrarisii*, Cause of Tomato Smut in Piedmont (Italy), 1065. *Ph. pithya* on *Pseudotsuga Douglasii* in Scotland, 1300. *Phoma* sp. on Cabbages, 338.

Phomopsis Pseudotsugae: On *Pseudotsuga Douglasii* in England, 345. In Scotland, 110.

Phorbia brassicae, 1310.

Phorocera claripennis: On *Neodiprion lecontei* in U. S. A., 786.

Phosgene: As Insecticide and Fungicide, 462.

Phragmidium subcorticium: On Roses in Morocco, 862. On *Rosa centifolia* in Italy, 452.

Phthorimaea: *Ph.* (*Lita*) *ocellatella*, on Beet in Germany, 1308. Prohibitive Measures Concerning Importation of Potatoes into Italy, 443.

Phyllophaga portoricensis: On Coconut in Porto Rico, 1307.

Phyllosticta Caricae-Papayae on Pawpaw in Natal, 1064.

Phyllotreta nemorum: On Soya Bean in Baden (Germany), 1191.

"Phylloxera", Vine: Pirovano Hybrids Resistant in Italy, 1127. Decrees regulating Distribution of Plants and Seeds in Italy, 96.

Physalis spp.: *Lema bilineata* in S. Africa, 354.

Physalospora: *Phys. baccae* on Vine in Japan, 1299. *Phys. Miyabeana* and Conidial Form (*Gloeosporium*) on *Salix purpurea* var. *angustifolia* in Japan, 1180.

Physoderma Debeauxii: On *Scilla maritima* in Italy, 452.

Phytophthora: *Phyt. cryptogea* and *Phyt. parasitica*: On Tomato, Control Methods in England, 1296. *Phyt. infestans*, *Phyt. Thalictri*, 1067. *Phyt. infestans*, and Effect of Copper Sprays, 340. On Potato in Morocco, 862. On Tomato in Victoria (Australia), 107. *Phytophthora* sp. on Peonies in Pennsylvania, 1067.

Pieris rapae: Inoculation Tests with *Micrococcus* (*Staphylococcus*) *acridicida* in Belgium, 1184.

Pineus strobi: On Weymouth Pine in Switzerland, 1193.

Pinus: *P. austriaca*, *P. Banksiana*, *P. palustris*, *P. ponderosa*, *P. resinosa*, *P. sylvestris*, *P. Strobus*, *P. virginiana*: *Neodiprion lecontei* in U. S. A., 486. *P. Cembra*: *Cronartium ribicola* (*Peridermium Strobi*) in Switzerland, 1193. *P. contorta* and *P. divaricata*: *Thelephora terrestris* in U. S. A., 869. *P. Laricio* var. *tenuifolia*: Cecidomyids and *Laspeyresia conicolana* in France, 467. *P. mariana*, *P. monticola* and *P. ponderosa*: *Thelephora terrestris* in U. S. A., 869. *P. ponderosa* and *P. rigida*: *Thel. fimbriata* in U. S. A., 869. *P. resinosa*, *P. rigida*, *P. Strobus*: *Rhagium lineatum* in N. America, 785. *P. Strobus*: Pests in Switzerland, 1193. *P. sylvestris*: *Botrytis Douglasii* in England, 346. *P. sylvestris*: *Hypoderma pinicola*, in Scotland, 234. *P. Strobus* var. *nana*; *Hypoderma strobilicola* in Scotland, 234.

Pipunculus industrius and *P. vaga-*

burdus: On *Eutettix tenella* in Idaho and California, 588.

Pissodes: *P. notatus* on Pines in Uruguay, 591. As an injurious Insect in Uruguay, 859. *P. pini* on Weymouth Pine in Switzerland, 1193.

Pisum arvense and *P. sativum*: *Laspeyresia novimundi* in Wisconsin, 164.

Pitangus sulphuratus: Nat. Enemy of *Castnia licus* in British Guiana, 1183.

Pittosporum undulatum: *Pulvinaria ornata* in New South Wales, 968.

Pityophthorus (*Bostrichus*) *micrographus*: On Weymouth Pine in Switzerland, 1193.

Plane: *Attacus cynthia*, 1071.

Plasmodiophora: On Cabbages, 338.

Plasmopara viticola: On Vine in Morocco, 862.

Platyedra gossypiella: On Cotton in Brazil, 1306. In Porto Rico (observed for the first Time), 1305. Machines for Treating Cotton Seed against *P. g.*, 1160.

Platynota flaveiana and *Pl. rostrana* in Texas, 870.

Platypus sp.: On Coconut in Porto Rico, 1307.

Pleospora: *Pl. infectoria* var. *aucubicola* on *Aucuba japonica* in Italy, 688. *Pl. Melissae* on *Melissa officinalis* in Italy, 452. *Pl. Pomorum*, probable cause of Spotting of Apples in England, 108.

Plociomera sp.: On Cotton in Brazil, 1306.

Plodia interpunctella: On Peanuts in California, 689.

Plums: *Attacus cynthia*, 1071. Chlorosis, in S. Africa, 957. *Penicillium italicum* and *Rhizopus nigricans* in S. Africa, 957. *Pseudomonas Pruni*, in Japan, 1297.

Podagrica malvae: On Hollyhock and Marsh Mallow in Crimea, 784.

Poinciana: *Euthyrhinus meditabundus* in Australia, 970.

Polistes spp.: Nat. Enemies of *Pseudococcus* in Cuba, 782.

Pollinia fulva: *Claviceps* sp. in Australia, 960.

Polycystis italica, 768.

Polygonum pennsylvanicum and *Polygonum* spp.: *Pyrausta ainsliei* in U.S.A., 783.

Polynema eutettixi: On *Eutettix tenella* in Idaho and California, 588.

Polyopeus purpureus: On "Spotted" Apples in England, 108.

Poncirus trifoliata: *Pseudomonas Citri*, 445.

Poplar: *Pemphigus populi-transversus* in New Zealand, 241. *Stilpnotia salicis* in Canada, 585.

Poppies, Field: Amongst Wheat, Control with Copper Sulphate, 963.

Populus alba, *P. balsamifera*, *P. monilifera* var. *angulata*, *P. pyramidalis*: *Stilpnotia salicis* in Massachusetts and New Hampshire, 877. See also Poplar.

Porcellio spp.: On Soya Bean in Baden (Germany), 1191.

Porto Rico: Diseases and Pests, 912. Of Citrus Fruits, 1061. Gumming (*Bacterium vascularum*) of Sugar Cane, 105. Injurious Insects to Coconut, 1307. Mosaic, Maize, 99. *Platyedra* (*Pectinophora*) *gossypiella*, noticed for the first time on Cotton, 1305. *Rosellinia* sp on Coffee, 866.

Portugal: *Oidium quercinum* on *Quercus racemosa*, 568.

Potato: "Canker" (*Synchytrium endobioticum*) of P. injurious to Tomato in Pennsylvania, 453. *Lema bilineata* in S. Africa, 354. Mildew, Aerial Tubers Resistant, 142. Mite in India, 696. *Phytophthora infestans* in Victoria (Australia), 107. In Morocco, 862. *Puccinia Pittieriana*, in Costa Rica and Ecuador,

444. *Sporidesmium* in Morocco, 862. Undetermined Disease in Morocco, 862 Prohibitive Measures concerning Importation into Italy of Tubers, etc. to Guard against introduction of *Synchytrium endobioticum*, *Phthorimaea operculella*, and the Coleoptera, *Doryphora decemlineata*, and *Epitrix cucumeris*, 443.
" Potts Seedling ", Apple var. Liablė to Spotting in England, 108
Poultry: Nat. Enemies of *Lema bilineata* in S Africa, 354. In Control of Insect Parasites in Orchards, 325.
Presoak Method: For Treatment of Seeds, 572.
Pristaulacus nigripes var. *duporti*: Obtained from larvae of *Xylotrechus quadripes* in Tonkin, 1075.
Pristodoryctes striativentris On Larvae of *Xylotrechus quadripes* in Tonkin, 1075.
Prodenia litura: On Rice in Goa (Portuguese India), 874.
Promiscolus sesquistriatus: Parasite of *Xylotrechus quadripes* and of *Chlorophorus annularis* in Tonkin, 1073.
Prospaltella: *Pr. aurantii*. On *Aspidiotus perniciosus*; *Pr. berlesei* and *Pr niigate* on *Aulacaspis pentagona* in Japan, 1185.
Prunus Buergeriana, *P. crassipes*, *P. donarium* subsp. *elegans* var. *glabra*, *P. Itosakura*, *P. japonica*, *P. Mume*, *P. Mume* var. *microcarpa*, *P Mume* var *Bungo*, *P. triflora*. Attacked by *Pseudomonas Pruni* in Japan, 1297.
Pseudococcus: *Ps. calceolariae* and *Ps sacchari* on Sugar Cane, in Cuba, 782. *Ps. citri*, on Cacao in the Dominican Republic, 1076. *Ps nipae*, on Coconut in Porto Rico, 1307 *Pseudococcus* sp: *Cryptolaemus montrouzieri* feeding on *Pseudococcus* spp. introduced into S. France, 1074.
Pseudomonas: *Ps Apii*, on Celery in States of New York and Michigan, 868 *Ps Citri* · Influence of Temperature and Humidity on growth of *Ps Citri* and its Plant Hosts and on Citrus Canker caused by this Bacteria, 445 *Ps. Pruni*: on Plum, Peach and other Rosaceae in Japan, 1297
Pseudotsuga: *Ps. Douglasii*: *Botrytis Douglasii* in Scotland, 346, 1300 *Chermes cooleyi* in England and Scotland, 971. *Hemerocampa pseudotsugata* in British Columbia, 590. *Phoma pithya*, 1300. *Phomopsis Pseudotsugae*, 1300. In England, 345. In Scotland, 110, 1300. *Ps taxifolia*: *Thelephora terrestris* in U. S A., 869.
Psylla isitis · On *Indigofera* in India, 446.
Psylliodes: *Ps. chrysocephala* on Soya Bean in Baden (Germany), 1101 *Ps. hyoscyami* on Belladonnà and Common Henbane in the Crimea, 784.
Puccinia: *P. Arachidis* on Peanut in Florida, 444. *P. Chrysanthemi*: on Chrysanthemum in S Africa, 957. *P. graminis* on Wheat in India, 446. *P. graminis*: on Wheat and Barley in Morocco, 862. *P. graminis* f. sp. *Tritici*: Biology in U. S. A., 611. *P. glumarum*: on Wheat and Barley in Morocco, 862. *P. Malvacearum*: on Wild Malvaceae in Morocco, 862. *P Maydis*: on Maize in Morocco, 862. *P. Pittieriana*. Origin of this Rust injurious to Potato in Costa Rica, 444.
Pulvinaria: *P. citricola* · Host of *Coccophagus lecanii* in Japan, 118[illegible]. *P ornata* on Citrus Fruits in New South Wales 968 *P. cellulosa*, *P. psidii* *P tecta*, 968

Pyrausta: *Pyr ainsliei* on *Polygonum* spp in U. S. A similar to *Pyr nubilalis*, 783. *Pyr nubilalis* on Maize in Canada, 585. *Pyr. penitalis* on *Nelumbium luteum*, 783
Pyroderces rileyi: In Texas, 870
Pythium De Baryanum: On Tomato in Victoria (Australia), 107

QUEENSLAND: *Chalcis euthyrrhini* on *Euthyrrhinus meditabundus*, Coleoptera injurious to Mango, 965. *Oncopera mitocera* on Pasture Land, 1190. *Tylenchus* sp on Banana, 466
Quercus: *Q. alba*: *Thelephora terrestris* in U. S A, 968. *Q dilatata* and *Q. incana*: *Calandra glandium* in India, 348. *Q racemosa* (*Oidium quercinum*) in Portugal, 568. *Q Robur* var. *pedunculata* (*Microsphaera*) in Switzerland, 568. *Q Robur* vars. *pubescens* (= *lanuginosa*) and *sessiliflora* (Perfect Form of Oak Oidium) in Italy, 568 *Quercus* sp *Microsphaera* in Italy, 568
" Queresa a forma de Estrella " (*Vinsonia stellifera*), 307
" Queresa destructiva " (*Aspidiotus destructor*), 307.

RAMULARIA: *R. variabilis* on *Digitalis purpurea* in Piedmont (Italy), 1065
Rats: Nat. Enemies of *Lema bilineata* in S. Africa, 354.
Rattus norvegicus: Toxicity of Barium carbonate, 357.
" Rayada ", Var Sugar Cane liable to Gumming in Porto Rico, 105
" Rayas amarillas " of Sugar Cane, 955
" Red Cross ", Wheat var susceptible to *Urocystis Tritici*.
Red Flour Beetle (*Tribolium castaneum*), 689
" Red Leaf ". of Cotton, due to Lack of Potash in St. Vincent (West Indies), 1004.
Red Legged Ham Beetle (*Necrobia rufipes*), 689.
Reduvidae spp.: Nat. Enemies of *Lema bilineata* in S. Africa, 354.
Rejuvenation (Treatment): Of Olives, Vines and Fruit Trees in General, 958
Remigia repanda: On Sugar Cane in British Guiana, 1183
Resistant Plants: Abaca (*Musa textilis*) to *Fusarium cubense* in the Philippines, 459. *Agave applanata* to *Colletotrichum Agaves* in France, 1061. Apples: " Allens Everlasting ", " Barnack Beauty ", " Belle Dubois ", " Christmas Pearmain ", "Fearn's Pippin ", " Gloria Mundi ", " Worcester Pearmain " Varieties immune to Spotting in England, 108. Barley: To *Helminthosporium gramineum* and *Heterodera schachtii* in Sweden, 144 To *H schachtii* in Sweden, 994 To Diseases in General at Mahndorf (Germany), 478. Bean. To Diseases in New York State, 377 Cabbage: to *Fusarium conglutinans* in U S A., 338 Cacao: " Calabacillo " Var Resistant to Diseases in Dominica (West Indies), 596. Cereals To Rust in Algeria, 1212. Cotton: to *Anthonomus grandis* in the Philippines, 722. Einkorn (*Triticum monococcum vulgare*) · To Black Rust (*Puccinia graminis*), 446 Lucerne: To Diseases in General in Mahndorf (Germany), 978. Moulds and Fungicides: Seed-coat injury and viability of Seeds of Wheat and Barley, 863 *Sitophilus oryza* in U. S A., 463 Toxic Gases: Effect of. 462
Septogloeum Arachidis: On Peanut in S Africa, 342
Septoria: *S Iridis* on Iris in Latium (Italy), 455. *S Lycopersici* on Tomato in New South Wales, 1179 *S Petroselini* var *Apii*, 868
Sesamia nonagrioides: On Sugar Cane etc, 158.
Setaria italica: *Ustilago Crameri* in Madras (India), 775
Sheets: Collection of Moroccan Crickets in Crau, 112
Shorea robusta: *Calandra shoreae* in Mauritius and India, 348 *Hoplocerambyx spinicornis* in E Bengal, 583
Silene inflata. Control in Canada, 579
Silkworms. Attacked by Muscardine (*Botrytis Bassiana*), 844.
Silvanus surinamensis: In shelled Peanuts, Dried Copra and Copra Products in California. 689
Silvestrina silvestrii var. *cecconiana* On Olives in Italy, 239.
Siphonophora ulmariae: On Soya Bean in Baden (Germany), 1191
Sisal (*Agave rigida*): *Colletotrichum Agaves* in Indo-China and French Sudan, 1061
Sitones sp: On Soya Bean in Baden (Germany), 1191
Sitophilus: *S linearis* (Tamarind Pod-Borer) in U. S A., 355 *S. oryza* (Rice Weevil) in U S A especially Florida, 463.
Sleepy Disease (Wilt) (*Fusarium Lycopersici*): Of Tomatoes, 107
" Small Moth Borer " (*Diatraea saccharalis*): of Sugar Cane, 1183
Smartweed Borer (*Pyrausta ainsliei*), 783
Smut: Millet, Italian (*Ustilago Crameri*), in Madras (India), 775. Onion (*Urocystis Cepulae*) in England, 454. Wheat (*Tilletia Tritici*), Control with Fungicidal Dust, 149.

"Mogarbia", Immune var. from Cyrenaica, 282. Noè Var. resistant in Italy, 810.

Smymothrips biuncinata: On Soya Beans, 1101.

Soya Bean: Pests observed in Baden (Germany), 1191.

Solanum: *S. aviculare*; *Phytophthora infestans* in Victoria (Australia), 107. *S. triquetrum* Wild; Rust in Texas, 444.

Solenopsis geminata: Protector of Aphids and Coccids harmful to Cacao Tree in Dominican Republic, 1076.

Sonchus oleraceus: Control in Canada, 579.

Sorbus japonica: *Pseudomonas Pruni* in Japan, 1297.

Sorghum: Mosaic, 99. Resistance to Uredineae in Morocco, 862.

Spain: Forest Insectarium, 1301.

Spanish Fly (*Lytta vesicatoria*): On Olive etc., 967.

Spathimeitenis spinigera: Parasite of *Neodiprion lecontei* in U.S.A., 786.

Spermophagus: *Sp. hoffmannseggi* on Cotton in Brazil, 1306. *Sp. pectoralis* (Mexican Bean Weevil) in California, 689. *Sp. subfasciatus* in Latium and Sicily, 580.

Spiders: Predaceous Enemies of *Acanthopsyche junodi*, 1186.

Spiraea chamaedryfolia: *Ceroplastes sinensis*, 405.

Spirospora Castaneae: On Chestnuts in France. 109. Probably synonymous to *Acrospeira mirabilis*, *Polycystis italica*, *Urocystis* (?) *italica*, and *Stephanoma italicum*, 768.

Spodoptera mauritia: On Rice in Goa (Portuguese India), 874.

Sporidesmium sp.: On Potato in Morocco, 862.

"Spotted Owlet" (*Athene brama*), 111.

Spotting: of Apples, in England, 108.

Sprayer: Pax Sprayer: 670. Reduced acidity in Oranges caused by certain Sprays. 609.

Spruce: Hypertrophy caused by exclusively Nitrogenous Nutrition, 797.

Stem-weevil (*Anthonomus grandis*) Control methods recommended for Cambodia cotton, 1221.

Stenommatus musae: On Banana in Hawai, 348.

Stephanoma italicum. 786.

Stilpnotia salicis: On Poplars in Canada, 585. On Poplars and Willows in Massachusetts and New Hampshire, 877.

St.-Kitts: *Pectinophora* (*Gelechia*) *gossypiella* on Cotton, 587.

St.-Vincent (W. Indies): Red-leaf of cotton etc. prevalent on Plots receiving no Potash, 1004.

Strategus: *S. quadrifoveatus* on Coconut in Porto Rico, 1307. *S. titanus* on Cacao in Dominican Republic, 1076.

Strawberry, Wild: *Rhabdopterus picipes*, in New York State, 356.

Straw-Blight (Take-all or Foot-Rot) (*Ophiobolus graminis* and *O. herpotrichus*): Of Wheat in Italy, 230. In New York State, 104.

Sudan, French: *Colletotrichum Agaves*, on *Agave* spp., 1061.

Sugar Cane: Gumming (*Bacterium vascularum*) in Porto Rico, 105. Injurious Insects; in Cuba, 782. In British Guiana, 1183. Mosaic, 99. In Cuba, 955. Red Rot (*Colletotrichum falcatum*) in India, 446. Root Disease; Kavangire var. resistant, 710. *Sclerospora Sacchari* (Sugar Cane Mildew) in the Philippines, 1177. *Sesamia nonagrioides*, 158.

Sunflower: *Bacterium Solanacearum*, 1062.

Sweden: Barley resistant to *Helminthosporium gramineum*, 144. To *Heterodera schachtii*, 144, 994. Wheat Diseases. 702.

Sweet Potato: Diseases in U. S. A., 719. *Tanymecus destructor* in S. Rhodesia, 348.

Switzerland: *Ctenophora atrata* on Birch, 876. Cockchafer: On the Resistance of the adult to High and Low Temperatures, 1072. *Cucurbitaria naucosa* on *Ulmus montana* in Canton of Vaud. 233. *Hypodeus glareolus* on White Fir, 699. *Microsphaera* on *Quercus Robur* var. *pedunculata*, 568. Pests of the Weymouth Pine, 1193.

Synchytrium endobioticum: Of Potato: Prohibitive measures concerning importation of Tubers into Italy. 443. Of Potatoes and Tomatoes in Pennsylvania. 453.

Systates chirindensis: On Coffee and *S. exaptus* on Maize in S. Rhodesia, 348.

TACHINA PHYCITAE: Parasite of *Mineola indiginella* in New Jersey. 875

Take-all (Foot Rot) of Wheat (*Ophiobolus graminis*), 104.

Tamarind: *Sitophilus linearis* in U. S. A., 355.

"Tambera": Caused by Undetermined Mite on Potatoes in India, 696.

"Tanglefoot", Means of controlling *Operophthora* (*Cheimatobia*) *brumata* and *Hybernia defoliaria* in France, 584. Control of *Solenopsis geminata* on Dominican Republic, 1076.

Tanymecus agricola on Maize and *T. destructor* on Maize and Sweet Potato in S. Rhodesia, 348.

Target Spot (*Alternaria Solani*): on Tomato in Victoria (Australia), 107.

Targionia merrilli: on *Rhizophora mucronata* in the Philippines, 117.

Tea: *Cephaleuros mycoidea* and *Pestalozzia Hartigii* in Ceylon, 393.

Tecoma leucoxylon: *Ovulariopsis obclavata* in Barbadoes, 231.

Telenomus californicus: Parasite of *Stilpnotia salicis* in Massachusetts and New Hampshire, 877.

Telphusa mariona in Texas, 870.

Tenebroides mauritanicus: on Shelled Peanuts in California, 689

Tennessee: *Sclerospora macrospora* on *Bromus commutatus* and on Wheat, 1059.

Tents, Rubber: In Fumigation of Trees with Hydrocyanic Acid, Sas, 872.

Termites: Destruction by Means of Chloropicrin, 114. In Sugar Cane Fields in Cuba, 782. In Brit. Guiana, 1183. *Mastotermes darwiniensis* on Mango in Australia, 970.

"Teroldigo": Trentino Vines and Behaviour as regards Diseases and Pests, 302.

Terre-gatée: Researches in Italy, 230.

Tetraneura: *T. agnesii* on olive, *T. flavescens* on Wild Barley and *T. reticulata* in Meadows in Italy, 347 *T. ulmi*, 233.

Texas: Lepidoptera likely to be confused with Pink Bollworm of cotton, 870. Rust on wild *Solanum triquetrum*. 444.

Thaumasura curculionis and *Th. pavo*: Parasites of *Euthyrrhinus meditabundus* in Australia, 970.

Thelephora caryophyllea. *T. fimbriata*. *T. terrestris*: On Forest Tree Seedlings in U. S. A., 869.

Thielavia basicola: On *Atropa Belladonna* in Italy, 452.

Thrips albopilosa, *T. discolor* (?), *T. major*, *T. longicollis*, *T. physopus*: On Soya Bean in Baden (Germany), 1191.

Thuja plicata: *Thelephora terrestris* in U. S. A., 869.

Tilletia: *T. Caries*: Norwegian Wheat, beardless with light ears very susceptible, 711. *T. Tritici* (?):

On Wheat in Morocco, 862. See also Smut

Tipula quaylii and *T. simplex*: On Pastures, Grain and Lucerne Fields in California, 873.

Tithymalus Esula (= *Euphorbia Esula*): Harmful Weed in U. S. A., 1070

Tobacco: *Lema bilineata* in S. Africa, 354 *Peronospora Hyoscyami* in Florida and Georgia, 687. "Tabac bleu", in Mauritius, Resistant, 504.

Tobacco Slug (*Lema bilineata*), 354

Tomato: *Bacterium exitiosum* in U. S. A., 867. *Bact. Solanacearum*, 1062. Diseases in Victoria (Australia), 107. *Phoma Ferrarisii*, Cause of Tomato Rot in Piedmont (Italy), 1065. *Phytophthora cryptogea*, *Phyt. parasitica* and *Rhizoctonia Solani* in England, 1296 *Phytophthora* sp. and *Septoria Lycopersici* in New South Wales, 1179. *Puccinia Pittieriana*, in Ecuador, 444 *Ramularia* sp. in Piedmont (Italy), 1065. *Synchytrium endobioticum* in Pennsylvania, 453

Tomicus quadridens: On Weymouth Pine in Switzerland, 1193

Tonkin: Nat. Enemies of *Xylotrechus quadripes* and of *Chlorophorus annularis*, 1075.

Toxoptera aurantii: On Cacao in the Dominican Republic, 1076.

Trametes radiciperda: On Weymouth Pine in Switzerland, 1193.

Trees: Forest: Control of *Euproctis chrysorrhoea*, in France, 694. See also Fruit.

Trentino (Italy): Behaviour of Teroldigo and Negrara Vines as regards Diseases and Pests, 302.

Tribolium castaneum: On Shelled Peanuts, Dried Coprah and Products of Coprah in California, 689

Trichogramma minutum: Egg Parasites of *Diatraea saccharalis* in Brit Guiana, 1183.

Trichothecium roseum: On Apples and Pears in Italy, 77

Tripoli: Effective Control of *Icerya purchasi* by *Novius cardinalis*, 461 Bramble-Leaf of Vine in Tripolitania. 1174.

Triticum monococcum vulgare (Einkorn): Very resistant to Black Rust (*Puccinia graminis*) in India, 446.

Tropaeolum majus: *Bacterium Solanacearum*, 1062.

Trypaneidae (= *Trypetidae*), 581.

Tsuga: *Ts. canadensis*: *Hemerocampa pseudotsugata* in Brit. Columbia, 590. *Ts. heterophylla*: *Thelephora caryophyllea* in U S A, 869

Tunisia: Diseases and Pests of Citrus Trees, 395.

Turkey Red: Wheat Var resistant to *Urocystis Tritici* in U S. A, 865.

Twitch Grass (*Agropyron repens*), 579

Tychea phaseoli: On Soya Bean in Baden (Germany), 1191.

Tylenchus sp.: On Banana in N. Queensland, 466.

ULMUS MONTANA: *Cucurbitaria naucosa* in the Canton of Vaud (Switzerland), 233.

United States: *Alternaria Nelumbii*, On *Nelumbium speciosum*, 778. *Bacterium exitiosum*, On Tomato, 867 *B. marginatum*, on *Gladiolus* spp., in Columbia and Illinois, 1066. *B. Solanacearum*, in Georgia, Florida and Alabama, 1062. *Ceutorrhynchus quadridens*: On Cabbage Seed Stalks in Long Island (N. Y. State), 1310. *Eutettix tenella*: On Sugar Beet in Idaho and California, 588. Foot Rot of Wheat in State of Washington, 104. *Fu-*

sarium conglutinans; Resistance of Different Varieties of Cabbage, 338. *Galerucella nymphaeae*: On *Nymphaea* (*Nuphar*) *advena* in New Jersey, 238. *Heterodera radicicola*: Resistant varieties of *Vigna sinensis*, 144. *Laspeyresia novimundi* on Peas in Wisconsin, 464. Lepidoptera on Cotton likely to be confused with Pink boll-worm (*Pectinophora gossypiella*) in Texas, 870. *Mineola indiginella*; On *Cotoneaster* spp. in New Jersey, 875. Mosaic, of Maize in Louisiana and Georgia, 99. *Neodiprion lecontei*. On Pines 786. *Peronospora Hyoscyami* on Tobacco in Florida and Georgia, 687. *Phytophthora* sp: On Peonies in Pennsylvania, 1067. *Pseudomonas Apii* on Celery, in States of New York and Michigam, 868. *Puccinia Arachidis* on Peanut in Florida, 444. *P. graminis* f. sp. *Tritici*, Biology of, 611. *P. Pittieriana*: On Potato, 444. *Pyrausta ainsliei*. On *Polygonum* spp., 783. *Rhagium lineatum*: On Pines 785. Rust, Comparative resistance of Oat Varieties, 376. Of Wheat in the Great Plains, 150. *Sclerospora macrospora*: On *Bromus commutatus* and Wheat in Tennessee and in Kentucky, 1059. *Sclerotinia minor*, on Celery, Lettuce etc., 574. *Sitophilus linearis*: On Tamarind, 355. *S. oryzæ*: On Cereals especially in Florida, 463. Smut, Hereditary of Resistance with certain Wheat Hybrids, 479, *Stilpnotia salicis* On Poplars and Willows in Massachusetts and New Hampshire, 877 *Synchytrium endobioticum*, on Tomato in Pennsylvania, 453. *Thelephora caryophyllea*, *T. fimbriata*, *T. terrestris*, on Forest Trees, 869. *Tipula quaylii* and *T. simplex*; on Grain, Lucerne, and in Meadows in California, 873. *Tithymalus Esula* (= *Euphorbia Esula*), Harmful Weed, 1070. *Urocystis Tritici*, on Wheat, 865. GENERAL. Diseases and Pests: Of Bean, Resistance to, in New York State, 377. Injurious Insects in California, 873. Of Citrus Fruits, 1011. Of Cotton, 388. Of Crops, 124. Of Potatoes, 719. Of Vetch, 48.

“URANIAGRÜN”, 693.

Uredineae, see Rust.

Urocystis: *U. Cepulae*: On Onion in England, 454. *U.* (?) *italica*, 768. *U. Tritici*: On Wheat in U. S. A., 865.

Uromyces: *U. Anthyllidis*: On Lupins. *U. appendiculatus*: On Beans; *U. Fabae*: On Beans, *U. Pisi*: On Peas and Vetches in Morocco, 862. *U. Rumicis*: On *Rumex Patientia* in Italy, 452.

Uruguay: *Aphelinus mali* (Importation and Acclimatisation) Parasitic on Woolly Aphis (*Eriosoma lanigera*) of Apple Tree, 692. *Pissodes notatus*, declared injurious to Agriculture, 859. Phytopathological Services, 335.

Ustilago: *U. Cynodontis* on *Cynodon Dactylon*; *U. Maydis* on Maize; *U. nuda* and *U. Hordei* on Barley; *U. Tritici* on Wheat in Morocco, 862.

Utethesia bella, *U. ornata*, on Cotton in Brazil, 1306.

VANILLA PLANIFOLIA: *Bacterium Solanacearum*, 1062.

Veronica speciosa and *V. salicifolia*: *Ceroplastes sinensis*, 465.

Vetch, Hairy: Diseases and Pests in U. S. A., 48.

Vetch, Common: *Uromyces Pisi* in Morocco, 862.

Victoria (Australia): *Claviceps* sp. on

Lolium perenne and *L. temulentum*, 960. Diseases of Tomato, 107.

Vigna: *V. Catjang*: *Alcides leucogrammus* in Rhodesia, 352. *V. sinensis*: Varieties resistant to *Heterodera radicicola* in U. S. A., 144.

Vine: Anthracnose, In Rio Grande do Sul (Brazil), 301; Nosiola, Trentino Vine resistant, 728. Black Rot (*Guignardia Bidwellii*), Prohibitive measures concerning Importation of Vines into Italy, 443. Bramble-Leaf (" Roncet "); observed in Tripolitania, 1174. Diseases Generally, Behaviour of Negrara and Teroldigo Vines in Trentino (Italy), 307. Diseases in Peru, 1230. Fungicides: Part played by Copper in Anticryptogamic mixtures, 340. Decomposition of Copper Fungicides on Surface of Vine Leaves attacked by Mildew, 1058. Mildew: In Rio Grande do Sul (Brazil), 301. Sirah Vine in Italy, Resistant, 512. 4401 de Couderc Direct Hybrid Bearer, Resistant in Portugal, 165. Oidium: *O. Tuckeri* in Morocco, 862. Sirah Vine in Italy, Resistant, 512. *Physalospora baccae* in Japan, 1299. *Plasmopara viticola* in Morocco, 862. Rejuvenation: Treatment for, 958.

Vinsonia stellifera: On Coconut in Porto Rico, 1307.

Vitis: *V. hederacea*: *Rhabdopterus picipes* in New York State, 356.

Vuitebœuf: Swiss Jura Wheat Resistant to Rust, 617.

WART DISEASE; Of Potato (*Synchytrium endobioticum*), on Tomato in Pennsylvania, 453.

Walnut: Anaerobic Bacteria and Gummosis in France, 343 Control of Diseases and Pests in France, 1123, " Nerume " or " Mal Nero " in Campania (Italy), 679. Over-wintering of *Marssonia Juglandis*, on Branches and Shoots, 101.

Wattle Bagworm (*Acanthopsyche junodi*), 1186.

" Wealthy " Apple var. susceptible to Rot (*Pleospora Pomorum*) in England.

Weeds, Harmful; Common Weed Seeds in Alfalfa Growing Districts in New South Wales, 493. Weed Control Measures in Canada, 579.

Weevil, Cabbage Seed Stalk Weevil (*Ceutorrhynchus quadridens*) in Long Island, New York State, 1310. Cotton Weevil, 722. See also *Anthonomus*.

" Wellington ": Apple Var. Suscepttible to Spotting in England, 108.

West Indies: " Calabacillo ", Cocoa var. immune to Diseases in Dominica, 596. *Pectinophora gossypiella*, on Cotton in Montserrat and St. Kitts, 587. *Ovulariopsis Gossypii* on *Gossypium barbadense* and *O. obclavata* on *Tecoma leucoxylon*, 231.

" West Indian Leaf Mildew " of Cotton (*Ovulariopsis Gossypii*), 231.

Wheat: Ergot (*Claviceps* sp.) in Australia, 960. *Erysiphe graminis* on Norwegian wheats with light Ears, very suscepible, 711. Field Poppy, Control of, with Copper Sulphate in France, 963. Formaldehyde Injury to Seed from Drying after Disinfection, 573. *Fusarium roseum* in Italy, 959. *Helminthosporium gramineum* in Emilia (Italy), 1295. Lodging: " Cignarellone ", Resistant var. in Molise (Italy), 283. " Mogarbia " Resistant Cyrenaica var., 282. Behaviour of Selected Todaro Wheats in Molise (Italy), 718. *Ophiobolus graminis* and *O. herpotrichus* (Foot-Rot), 104, 230. *Puccinia graminis*, 446. *P. graminis* f. sp. *Tritici*, 446. Biology of, 611. *P.*

graminis and *P. glumarum* in Morocco, 862. Rust: Behaviour of Varieties in the Great Plains, U. S. A., 150. Behaviour of Todaro Wheats in Molise (Italy), 718. Effect on Respiration and the Metabolism of Plants attacked, 24. Bretonnières and Vuiteboeuf, Swiss Jura vars., resistant. 617. Comparative Resistance of Crosses, 30. "Cignarellone" var. in Molise (Italy), resistant, 283 Saprophytic Fungi and Injuries to Seed Coat and Viability of Seeds, 863. *Sclerospora macrospora* in Tennessee and Kentucky, 1059. Smut: Control with Fungicidal Dusts, 449. Inheritance of Resistance to Stinking Smut in U. S. A.. 479. "Mogarbia," Cyrenaica Var. resistant, 282. Noé, Resistant var. in Italy, 810. *Tilletia Caries*, Norwegian Var. with light Ears, very susceptible, 711. *Urocystis Tritici*: Introduction into U. S. A., 865. Comparative resistance of Certain varieties in U. S. A., 865. *Ustilago Tritici* in Morocco, 862. General: Diseases: In Parana (Brazil), 285. In Sweden, 702. Resistant varieties in Mahndorf (Germany), 478.

" White Creole ", Maize Var. attacked by Mosaic in Louisiana, 99.

White Fly of Citrus Fruits (*Aleyrodes citri*): Prohibitive Measures concerning Importation of Fruits into Italy, 443.

Willow: *Stilpnotia salicis* in Massachusetts and New Hampshire, 877.

Wilt, Bacterial (*Bacterium Solanacearum*) on Castor Bean in U. S A., 1062.

Wilt, Indigo (*Indigofera arrecta*) in India, 447, 1057.

Wilt, Tomato (*Fusarium Lycopersici*) in Victoria (Australia), 107.

Wisconsin: *Laspeyresia novimundi* on Peas and Field Peas, 464.

" Wisconsin Brunswick " and " W Hollander ": Cabbage vars resistant to *Fusarium conglutinans* in U. S. A., 338.

Woolly Aphis (*Eriosoma* [*Schizoneura*] *lanigera*), 692.

" Worcester Pearmain ", Apple var. Immune to Spotting in England, 108.

XANTHIUM COMMUNE: Harmful Weed in New South Wales, 1182 *X. Strumarium*, 1182.

Xyloterus (*Tomicus*) *lineatus*: on Weymouth Pine in Switzerland, 1103.

Xylotrechus quadripes: Nat. Enemies of this Coleopteron in Tonkin, 1075.

" YELLOW CALEDONIA ": Sugar Cane var. Immune to Gumming (*Bacterium vascularum*) in Porto Rico, 105.

" Yerba mora " (*Sarache* sp), 444.

ZENODOCHIUM CITRICOLELLA: In Texas, 870.

Zenodoxus palmii: In Texas, 870

" Zikugare " (*Physalospora baccae*), 1299.

Zinc Compounds, 684.

Zizyphus Spina-Christi: *Trypaneidae* in Egypt, 581.

OF AGRICULTURAL INTELLIGENCE AND PLANT DISEASES

ABSTRACTS

AGRICULTURAL INTELLIGENCE

GENERAL INFORMATION

1 – **Agriculture in Persia (Persian Products, Rich and Varied Resources).** — *The Times Trade Supplement*, Vol V, No 70, p 135 London, 1920

Agriculture is by far the most important of the Persian industries, in spite of which the demand for agricultural products largely exceeds the supply With the advent of railways, exports as well as imports will come into far greater prominence than hitherto, but it is difficult to see how agriculture can benefit to any appreciable extent unless the present irrigation systems are revolutionised

The soil of the country is decidedly suitable for the many and varied crops grown When water is available two or even three crops can be raised annually Fruit and other trees when planted under suitable conditions are prolific in growth Wheat, barley, rice, opium, cotton, tobacco, lucerne, clover, peas, beans, and various root crops, including sugar beet, all yield an abundant harvest. Various oil-producing plants such as linseed and castor oil, do equally well. A large quantity of Persian wheat finds its way into the English market, and possessing as it does special qualities, it is most valuable for mixing with British and other wheats ; it is not surprising, therefore, that the demand for this cereal is greater than the supply. Tobacco is grown extensively in the Ispahan and Shiraz districts, a large part of which is bought up by Levantine merchants.

Hitherto the Persian cotton crop has almost entirely been absorbed by Russia. There is much room for experiment and development in the cultivation of cotton, especially with a view to growing the most suitable varieties for the English market.

Persian opium is much sought after in the London sale rooms, because of the large percentage of opium content, and can easily compete with that grown in any other part of the world.

There are great possibilities in the cultivation of sugar beet. Persia at present relies entirely on the outside world for its sugar supply; the consumption per head works out at a very high average. With very little enterprise, sugar could be manufactured on the spot, and a sugar factory would prove to be really paying concern.

Vegetable oils are not exported to any great extent, but there is no reason why this industry should not be developed, especially in view of the increasing demand for vegetable oils.

The climate of the Persian highlands is in every way suitable for fruit cultivation. Apricots, peaches, nectarines, pears, grapes, plums, cherries, figs, and almonds all grow to perfection. The Ispahan melon has been judged by an American horticultural expert to be the finest in the world. This special melon can be stored for at least six months, but so far has not been exported. Canned and dried fruits, fruit pulp, and jam could be exported on a large scale if once these industries were seriously taken in hand.

The two essential things necessary for the development of Persian industries are improved communications and the establishment of various irrigation systems. So confident are many Persian financiers and landowners as to the success of a scheme for irrigating the Ispahan plain that with little inducement they would provide half the necessary capital. The many thousands of acres that are not under cultivation owing to water shortage could be leased at a very moderate sum or bought outright from the Persian Government. Local farmers when once assured of a good water supply would readily pay the rental and water dues demanded. There is little doubt that such an undertaking, once launched, would prove a great success.

2 - **Nutritive Value of the Proteins of Barley, Oat, Rye and Wheat Kernels.** — OSBORNE, T. B., MENDEL, B , and WAKEMAN, A. S (Laboratory of the Connecticut Agricultural Experiment Station and the Sheffield Laboratory of Physiological Chemistry, Yale University, New Haven), in *The Journal of Biological Chemistry*, Vol. XLI, No. 3, pp. 275-306, tables 5, charts 13 Baltimore, March, 1920.

The deficiency in certain of the essential dietary components, notably specific inorganic elements and fat-soluble vitamine has led to the general conviction of investigators that none of the common cereal grains alone or even a mixture of them, suffices to afford satisfactory nutrition. The foremost remaining dietary factor in these seeds is protein and the writers consider that the misconception of the possible value of cereals as sources of protein is due to lack of realisation that in the form in which these grains are most commonly fed, the sum total of their various proteins must be taken into account.

Investigations were resumed with white rats in attempting a further study of the relative nutritive value of the cereal proteins (1) by feeding with entire cereal grains, finely ground, together with an adequate 3 % salt mixture and 5 % butter fat to supply the fat soluble vitamine, on the assumption that these grains would supply sufficient water soluble vitamine. Where necessary, enough maize starch was added to make the total protein of the ration 5.8 or 10 % approximately. In this way the proteins of barley, oats, rye and wheat were compared.

---

(1) See *R.* Oct, Dec 1919, No. 1175.

[1-2]

Barley. — The experiments leave no doubt as to the adequacy of barley proteins as a whole, for the nutrition. From the evidence secured by STEENBOCK, KENT and GROSS (1) regarding the content of water soluble vitamine in barley, the lack of the latter may be considered the cause of poorer growth in the authors' experiments with diets containing only 5 % barley protein. The rats on the 5 % protein diets ate as much total food i. e. calories, as those of the same size on higher concentrations. New experiments furnishing a ration low in protein but adequate in water soluble vitamine were carried out. The diet was the same as in the earlier series but with the addition of approximately 18.6 mg. daily, apart from the food of a protein free vitamine preparation from yeast. The food intakes showed no noteworthy increase, nor was the gain per gm. of protein eaten, more favourable; hence the slow growth on the 5 % ration can still be ascribed to the comparatively small quantity of protein afforded by diet.

Experiments were carried out on similar lines with oats (1), rye, and wheat and charts illustrate the comparative nutritive efficiency of these kernels. The comparative equality of the four types of cereal proteins becomes more stiking when the gains which they promote per gram of protein consumed are contrasted with those secured within comparable periods of growth by the use of proteins from other sources. The advantage of more efficient supplementary protein to the cereal protein has previously been discussed (2). The utilisation data secured by the authors, testifies to the unexpected availability for growth of the proteins of these whole cereals, and is in harmony with the work of SHERMAN and collaborators (3) connected with the maintenance metabolism of adults as shown by nitrogen balance experiments on diets in which the proteins of oats and maize contributed a large portion of the protein intake. These results showed that for purposes of practical dietetics equal weights of oat and maize proteins may be regarded as essentially equal in value, and even the minimum amount of milk which can possibly be regarded as permissible in the light of the present knowledge of nutrition will apparently so supplement the protein of either the maize or oat kernel as to make them function with an efficiency comparable with that of the average protein of mixed diet in the maintenance metabolism of man.

The authors note that the sufficient, successful prolonged growth observed in the case of all the cereal studies, makes it unlikely that the protein factor is responsible for the untoward outcome of many of the cereal experiments undertaken hitherto.

3 - **The Antiscorbutic Property of Vegetables. An Experimental Study of Raw and Dried Potatoes.** — GIVENS, M. H and MC CLUGAGE, H. B. (Department of Physiology, University of Rochester), in *The Journal of Biological Chemistry*, Vol. XLII, No. 3, pp 491-515, table I, Charts XVII, bibliogr. of 13 works, Baltimore, July, 1920.

Reports have already been published that under certain conditions, cabbage (1), tomatoes (2) and orange juice can be dehydrated so that the resultant dried products retain a significant amount of the antiscurvy vitamine. The authors continued their studies on similar lines in order to ascertain whether the antiscorbutic vitamine in potatoes is destroyed at definite temperatures during drying quite apart from the value of the nitrogen-containing compounds (3) and the content of inorganic salts and water and fat-soluble vitamines (*Journal of Biological Chemistry.*, Vol. XXXVI, p. 197, 1918) previously under investigation elsewhere.

The experimental animals were healthy young guinea pigs. The basal diet used to produce scurvy was made of heated soya bean flour, milk, yeast, paper pulp, calcium lactate and sodium chloride. The daily allotment of undried samples was 10 gm., per animal and of dried and cooked potatoes, 2.5 gm. On this basis every animal received approximately the same amount of total solids of potatoes equivalent to that contained in 10 gm., of the raw material. The different ranges of temperature for drying were 35 to 40°, 55 to 60°, and baking at 204° and then drying at 35 to 40°C.

A review of the appended charts shows the results with differently treated potatoes considered as antiscorbutic supplements to the basal soya cake diet. A temperature of 35 to 40°C for 6 to 8 hours was apparently more destructive than 55 to 60° for 4 to 6 hours, and the latter was hardly as destructive as 75 to 80°C for 2 to 3 hours. This conclusion was based on the results obtained with potatoes dried at those temperatures and fed uncooked and cooked for 15 minutes at 100°C. With 2.5 gm, dried at 35 to 40°C and fed without further treatment, death from scurvy was slightly delayed; with 5 gm., life was certainly prolonged. If the dried products were further heated in water at 100°C for 15 minutes and then fed in amounts equivalent to 2.5 gm., of dried material, there was no evident protection with the 35 to 40° and 75 to 80°C products, but there was certainly some with the 55 to 60°C material, potatoes baked and then dried gave a product which possessed antiscorbutic potency.

From these results it is assumed that the factors involved in the destruction of the antiscorbutic vitamine include not only the degree of heat and the duration of heating, but also the enzyme content and the reaction of the food being dried. The authors assume also that at any temperature below 80°C, the enzymes are functionating. All potatoes dehydrated below this temperature darkened during the dessication.

[2-3]

The minimum amount of raw potatoes which will protect a guinea pig against scurvy has not been determined but the feeding curve indicates that slightly less than 10 gm., per day was about the lowest limit to suffice for protection.

As a result of former experiments with pigeons and with rats (GIVENS and COHEN), the experimental diet employed apparently contained among its satisfactory components the fat-soluble and water soluble vitamines. But the effect on guinea pigs and the necessary addition of a new vitamine to prevent spread of scurvy, conformed the belief that there is an antiscorbutic vitamine. OSBORNE and MENDEL (1) found that 0.2 gm., of dried brewers' yeast per rat per day was sufficient to promote normal growth. The basal diet used for producing scurvy contained more than twice that amount. There is no base to warrant the allegation that the drying of the basal diet or potatoes destroyed either the fat or water soluble vitamine.

The results with fresh potatoes cooked and those dried at 35 to 40°C and then cooked, confirm those of former investigation, (HOLST and FRÖLICH, *Zoological Hygiene*, Vol. LXXII, p. 1, 1912 and CHICK and HUME, *The Lancet* Vol. II, p. 774, 1918).

4 - **Some Nutritive Properties of Nuts; their Proteins and Content of Water-Soluble Vitamine.** — CAJORI, F. A. (Sheffield Laboratory of Physiological Chemistry. Yale University), in *The Journal of Biological Chemistry*, Vol. XLIII, No. 2 pp. 583-606, tables 3, charts 8, bibliogr of 31 works, Baltimore, M. D., September, 1920.

The conclusion, based on chemical analysis, that nut proteins are of high biological value. has been verified by the experiments of JOHNS, FINKS and GERSDORFF with the coconut (2) and DANIELS and LOUGHLIN with the peanut (3). These investigators observed normal growth in young rats on diets in which the coconut and peanut furnished the sole source of protein. The author extended feeding observations on nuts to include the almond, English walnut, filbert, pecan and pine nut. Young rats were fed on diets complete in respect to every dietary essential for growth, provided the proteins were of a character to support growth. Nut proteins made up approximately 18 % of the diets.

Examination of the growth curves shows that the growth resulted at a normal rate on all diets except when 'pecan supplied the protein. The animals on this diet grew at a rate of about two thirds normal during the nine weeks test. When one-third of the pecan protein was replaced by casein, a marked rise in the rate of growth was noted. More experiments are necessary before final conclusions can be drawn regarding the comparative efficiency of the pecan proteins. The author states that by accepting the opinion of OSBORNE and MENDEL (3), it may be concluded from the results of these experiments, that the almond, English walnut, filbert and pine nut are sources of protein adequate for nutrition. These were also found to furnish the necessary nitrogen complexes for the elaboration of milk in rats. The approximate quantitative idea of the comparative distribution of water soluble vitamine amongst these plant products was obtained.

---

(1) See *R.* Feb. 1920, No. 157.

(2) See *R.* April, 1919, No. 439.

(3) See *R.* July, 1918, No 785.

A daily dose of 2 gm., of hickory nut, pine nut and pecan, respectively, or the inclusion of 27 % of almond, or filbert and 19 % english walnut in the food was found sufficient to enable animals that had declined on the basal diet, namely ; Casein, butter fat, inorganic salts, starch and lard, and with an obvious lack of water. soluble vitamine, to recover rapidly and resume growth. 1 gm. of English walnut, black walnut, hickory nut or pine nut proved to be an equally efficient restorative agent. The chestnut, English walnut and pecan appeared to be especially potent, daily doses of 0.5 gm., sufficing to permit slow growth. A comparison of the growth curves indicates that the almond was not so efficacious as a source of water soluble vitamine.

5 - Agricultural Instruction in the Former Austro-Hungarian Empire during the War (1). — Communication by M. H. Kallbrunner, *Austrian correspondent of the International Institute Agriculture.*

During the war very little was done in all the belligerent countries that had not a direct bearing on the issue at stake. It is true that, as shown in the appended data, the number of schools had increased, but a good number had to be closed, partly because the teachers and elder pupils had been called to the colours, partly because some schools were situated in the war zone, and partly because owing to the scarcity of labour, parents were obliged to keep their children to work at home. The schools that were still kept open were so poorly attended that instruction was necessarily suspended.

The data shown in the appended table are taken from the *Land und Forstwirtschaftliche Unterrichtszeitung*, Parts I e II, Vienna 1918.

The following are a few notes on the Table: —

The " Hochschulen " only accept pupils who have taken their secondary school classical (" Gymnasium ") or technical (" Realschule ") diploma. These schools are situated at: (1) Vienna, where there is a section for forestry and cultural technique branches ; (2) Prague where it is affiliated to the University ; (3) Cracow, affiiliated to the " Technische Hochschule. " All these institutions, during the war, had exceptionally few pupils, as these were just of the age for military service.

The higher Agricultural College (" Hochschule für Boden Kultur ") at Vienna held courses during the war for refugees from the war zone, disabled men and those unfit for service. The number of students at the school was 464 in March, 1918, and after the Armistice the number rose to over 2000 but soon felt to 1200 which was fortunate, as the school could not accomodate such large numbers. After the partition of the Empire new

Agricultural schools were soon established in the new States at Brünn, in Czecho-Slovakia and at Agram, in Yugoslavia.

The Schools of Arts and Crafts (" höhere Fachschulen ") are known as " Akademien " and give a years instruction to those students who have failed to obtain their secondary school diploma, but have been shown to possess a standard of education corresponding to that necessary in former Austria to obtain the right of one years free instruction. There was one of these Academies at Tabor, where the teaching was in Czech, one at Tetschen-Liebwerd, where the teaching was in German, although the Academy is now in Czeco-Slovakia, and a third is at Dublang where the teaching is given in Polish. Moreover at Vienna there is a Brewing School (" Akademie für Bramindustrie "), but it was closed during the war. At all these institutions there were at that period special courses open for disabled men who were previously engaged in agricultural work and also for those who were unable to follow their former profession and wished to take up a new one. Many of these were under the impression that agriculture could be learned in a few weeks, but they were sadly disillusioned. They were unsuccessful at the practical work and they could either obtain no employment at all or had to content themselves with a very modest employment. Better results were obtained with men who specialised and could make some use of their former experience, the most successful courses being those training men for driving motor-ploughs, all types of steam-engines drainage, etc. Besides these courses special courses have been organised, as in pre-war days, for subjects such as forestry, horticulture, dairying, etc. and agricultural instruction for teachers.

The " Landwirtschaftliche Mittelschulen " admit youths who had attended all 4 classes of an ordinary " middle " school. As the pupils in all four classes were often under military age, the numbers, expecially in the lower classes, were comparatively high. But there were cases where the higher classes had so few pupils that it was decided to suppress or amalgamate them with others. In order to obtain the best possible results in cultivating the fields from those members of the staff who were not on military service, numerous courses were held in these schools, special attention being given to the training of the disabled and courses were arranged on pisciculture, bee keeping, book-keeping, agricultural improvements, arboriculture and gardening, and at the middle forestry schools (" Forstlichen Mittleschalen), on forest protection and exploitation type-writing, etc.

The Middle School of Agriculture Laa-an-der-Taya is worthy of special note, as on account of its high grade of teaching it is aspiring to be nominated as an Academy and seeks particularly to get in touch with agriculture practice (1). During the first 2 years the students do not attend the school very much, but live on a neighbouring farm where they learn the practical side under the supervision of the school which gives them weekly theoretical lectures. All that they have seen is discussed, and by this means the interest of the students is stimulated. The students are also taught how to keep the books. The pupils usually remain for one year on a small farm, then spend a second year on a large farm where they learn how to cope with entirely different conditions.

---

(1) See *Programm der höheren landwirtschaftlichen Lehranstalt in Lae a. d. Taya, Niederosterreich Selbstverlag.* (*Ed.*)

But this means the student receives a more thorough instruction than in a school to which a farm is attached, but where the student has no chance of doing practical work and thus learning the work in all its details It is certain that the new methods of instruction will prove successful The author considers it especially advantageous that the young student should learn the practical side of farming in this way before studying its theory, so that he still has time to change his studies if he finds that he is not suited to farming. The pupil at the ordinary schools begins field work at a relatively advanced age and if it does not suit him he can hardly change; being obliged to continue without the taste or aptitude for his profession. An agricultural school for girls was started at Otterbach (Upper Austria) in 1911 and another at Lemberg (Galicia) in 1913. These two schools gave 2 courses. During the war an agricultural school for girls and a " normal " school for teachers of domestic economy, both giving 3 courses were established at Bruck-am-Leitha (1).

The elementary agricultural schools (" niederen Landwirtschaftschulen ") are divided into 2 groups. The first, school for farmers (" Ackerbauschulen "), gives instruction all the year round; the second, winter schools (" Winterschulen ") are usually open from November to the end of March. During the war all these schools suffered, partly owing to shortage of manual labour, and partly owing to the departure of the older pupils for military service. The only method which could be adopted by farmers was to keep their children at home to work. In addition, many of the elementary schools were in the war zone so that all instruction in them was impossible. The schools were kept open only by running numerous short courses, which enabled the children of the peasants to attend. Now they are working normally, the attendance being very large. The grave financial position of the State has seriously affected agricultural instruction, which is relatively, expensive. It can be seen from Table I that the number of grants to assist the children of poor farmers to study is constantly decreasing, which hinders some of the more industrious and intelligent students from continuing their studies. It is just the same with the means of instruction . With regard to this, the decrease in numbers of private schools and those governed by societies, is very noticeable, as they now mostly lack the means to enable them to prosper and they would be glad to become public institutions. This decrease would have been much greater if there had not been some new foundations, especially of small schools which are dependant on societies.

---

These difficulties were present before the war, but the lack of coal and the shortage of teachers made matters very much worse, necessitating closure in some cases. These difficulties will be felt still more in the future when competition becomes more acute, if the proper training of technicians is entirely lacking for several years.

Certain organisations and political leaders have demanded that the director of any farm should possess a certain minimum of elementary education, without which no-one should be allowed to farm; thus a farm of a certain size ought to be managed only by a person with a higher Agricultural Diploma or that of a middle school plus a double period of practical work. But most of the high posts are already filled by men not conforming to these standards and these efforts, praiseworthy in many respects, cannot succeed, an additional factor being the shortage of suitable candidates. These projects are opposed, and justly, by those who maintain that instruction in a school is not everything and can often be replaced by practical experience; further if a student desires to obtain technical instruction he will do so without being compelled (1).

By a Government Order issued in 1916 those who have obtained the Higher Diploma of the Agricultural Schools have the right to bear the title of engineer.

Unfortunately, Austria completely lacks agricultural finishing schools ("landwirtschaftliche Fortbildungsschulen"), although these are being demanded on all sides (2). A scheme has also been proposed by which travelling schools would be formed, to visit sufficiently large villages, staying one year at each in such a way that after a certain time the school would return to the same place so that a group of young men would be able to attend again, and the majority of farmers be able to would follow supplementary courses. In Czecho-Slovakia a law has been passed authorising the formation of supplementary schools, but it, is impossible to say yet whether it is practicable.

The most important school for the farmers is the elementary "Volksschule," which should supply a good preliminary education which would fit children for their intended profession, in the best way possible. Unfortunately the Austrian elementary school is far from filling these requirements, but it can be stated that the matter is being taken in hand by the Austrian School Administration.

The following Table is taken from the *Oesterreichische Statistiches Handbuch für das Jahr* 1916-1917, pp. 11 and 55, Vienna, 1918.

Compulsory education for several years was first introduced into Austria in 1774, becoming compulsory during the reign of Joseph II (*d.* 1790). During the last 50 years, however, a modern law, brought in by M. HANSER

TABLE II. — *Number of illiterate persons, and the average unit in Austro-Hungary.*

District	Illiterates of both sexes per 100 inhabitants over 10 years of age,	Average annual production in 1903-1913 in quintals per hectare	
	Per cent	Wheat	Oats
Upper Austria	2.4	14.4	11.3
Lower Austria	1.7	13.5	12.0
Salzburg	2.9	14.6	6.4
Styria	7.9	9.9	10.6
Carinthia	12.3	10.3	10.7
Carniola	12.2	7.7	9.6
Trieste	8.5	6.6	5.3
Gorizia	15.5	8.3	9.5
Istria	39.8	5.2	4.1
Tyrol	2.4	13.4	10.6
Vorarlberg	0.8	8.0	6.6
Bohemia	2.1	16.3	14.8
Moravia	2.9	14.3	12.5
Silesia	3.7	11.7	11.5
Galicia	40.6	10.3	10.2
Bucovina	53.9	13.3	13.7
Dalmatia	62.8	6.0	4.1

concerning elementary schools gives, in Art. 75, ample scope for the peasants to evade compulsory education.

It is interesting to note that in those parts of Austria with a population largely illiterate and where compulsory education is not enforced, lack of education goes hand in hand with low production.

6 - **Domestic Economy and Agricultural Schools for Girls in Italy.** — SAVAZZINI, G., (Director of the Cattedra di Agricoltura, Ossola), in the *Giornale di Agricoltura della Domenica*, Year XXX No. 47, pp. 371, figs. 2. Piacenza, Novem. 21, 1920.

The only girls schools of this type are: A practical agricultural School for Girls at Niguardo (Milan), an Agricultural Domestic Economy school at Florence (Cascino), affiliated to the School of Pomology, and a Domestic Economy School at Bergamo. General GIBELLI, of the agricultural committee of Milan, has organised several domestic economy schools, but more for the young factory girls than for daughters of peasants.

The author asks the local Ambulatory Chairs of Agriculture to advocate the establishment of these schools wherever small holders are numerous. As an example he describes the working of the School of Domestic Economy and Agriculture of Ossola, which he founded at Varzo (near Domodossola, province of Novara) and which is equipped for practical instruction in domestic work, cheese making, field cultivation etc.

[5-6]

The students are divided into groups, which carry out the various tasks in turn, in a way similar to that practised in the Belgian agricultural Schools for girls (1).

7 - **The Italian Agricultural Society.** — *Atti della Societa agronomica italiana*, Year 1, No 1, pp. 1-27. Rome, 1920.

On July 18, 1920, the Italian Agricultural Society was formed by Italian scientists engaged in the study of agricultural problems for the purpose of encouraging and co-ordinating scientific research and experimental work in agriculture and related industries.

The programme of the Society is as follows: —

(1) To institute, organise and assist scientific research and experiments.

(2) To inquire into agricultural problems.

(3) To provide scientific criticism of the Italian agricultural movement and of all manifestations by public bodies in relation to agricultural study.

(4) To undertake and help publications in conformity with the aims of the Society.

(5) To institute a department for scientific documentation.

(6) To manifest, eventually, activity in a consultative capacity

The following foundamental principles, proposed by Senator Prof. GRASSI, were adopted:

I. — The Society relies chiefly upon the individual efforts of the members. Each specialist in a certain branch may report a problem or group of problems to the directing Council, which has the task of directing the activities of the Society by organising study and research on a large scale, by encouraging young workers and by coordinating ideas and experiments.

II. — That pressure should be brought to bear on the Government to make it consider schemes put forward by the Society and provide the necessary means.

The Society will begin its work by the organised and systematic study of the following 5 subjects with upon the help of its members and the technical and financial support of all those who study or are interested in such subjects:

(1) Research concerning the best method of utilising arid soils for the cultivation of crops of economic importance paying particular attention to their resistance to the dryness of the substratum (BORZÌ).

(2) Determination of the yield capacity of soils in the south of Italy, chiefly in connection with their exposure and the cultivation of wheat (RIVERA).

(3) Research on the utilisation of leucite as a source of potash especially as regards Italian agriculture (BORGHESANI).

(4) Research on the causes of citrous root rot (BORZÌ).

(5) Research on insects harmful to the olive (GRASSI).

CROPS AND CULTIVATION

8 - **Agricultural Climatology of Australia.** — TAYLOR, GRIFFITH, in *Quarterly Journal of the Royal Meteorological Society*, Vol. XLVI, No. 196, pp. 331-356, figs. 9, bibliography of 7 works, London, Oct. 1920.

WHEAT. — This crop is by far the most important in Australia, and constitutes 69 % of the area cultivated. Only in Queensland (26 %) and Tasmania (10 %) does it occupy a subordinate position. Table I indicates the production and climatic controls in the several States.

The primary control is the rainfall, but it is not the total precipitation so much as the amount which falls during the growing period which determines the wheat belt.

There are obviously vast areas suitable for wheat which have not yet been developed. In the early stages of wheat growing in Australia, mistakes were made and progress was slow. Cultivation was confined to the moist coastal country with its annual rainfall of 30 to 40 inches.

TABLE I. — *Wheat* 1917-1918.

State	*Bushels*	Temperature April-Oct.		Rainfall April-Oct.	
		Whole	Optimum	Whole	Optimum
New South Wales	37 800 000	16.11° – 11.11°	16.11° – 11.11°	625–225	375–275

Victoria	74 616	4 200
Sout Australia.	46 980	3 700
Tasmania	26 215	340
Total . . .	**484 330**	**15 470**

It was only later on that the discovery was made that wheat could be grown much more successfully in districts where the rainfall is 25 inches or under. On well worked *fallowed* land it is stated that splendid crops have been harvested, although the rainfall only amounted to 2 or 3 inches during the growing period. However, it is not the quantity of rain which is important but also the time of year in which it falls. Rain is wanted in the early autumn so that ploughing can be done, and in the spring when the wheat is heading and flowering. Rain in April and May, and again in September or October, ensures a fine crop. The summer is usually dry and warm which conteracts the fear of rust and facilitates hay making.

In districts which have most of the rain in the summer, wheat cultivation becomes practically impossible. Swanland (W. Australia) and New South Wales, present in this sense the two extremes; in the former the rainfall in winter is reliable, and in the latter the summer rains are unreliable and therefore contrary to wheat growing.

In most of the wheat areas the crop depends very largely on the rainfall stored in the soil from the previous year. The actual rainfall during growth may be only 7 inches or even less, but this is supplemented by the fall while the land is lying fallow.

In New South Wales, the practice is to plough the land in July or August to a depth of 4 1/2 to 5 inches, and then to let it lie for 6 weeks, when it is harrowed. The fallow receives frequent workings with the cultivator so as to form a loose mulch, which checks evaporation. This operation is repeated, until sowing time in April or May. The majority of districts enjoy an annual rainfall of 20 inches or less, and only from 6 to 8 inches of this falls during the growing period.

In New South Wales, the most productive region is the Riverina around Corona, and thence north to Molong. The county of Hume is a probably the most productive centre for Australia. The relation between the wheat isopleths and the winter isohyets is extremely close. The 10-inch line is the western boundary of the wheat area, whilst a rainfall of over 20 inches in the wheat period practically fixes the eastern boundary of the State, for only around Sydney is a little wheat grown in wetter districts.

But, until the railways are much more numerous, there will be large areas of wheat land unoccupied. The farthest distance from the railways to make wheat growing profitable, should not exceed 18 or 20 miles.

A revolution in wheat growing may be said to have taken place with the advent of " Federation " wheat and other new varieties produced by **Farrer**. Such an extensive range is provided, that farmers can now begin sowing at the end of March, and continue through April, May and June and finish with certain varieties at the end of July. The early sown varieties ripen later, and so the harvest ripens in stages and can be more readily handled.

In Victoria, the greatest area under cultivation lies in the north and north-west. The countries of Rodney, Moira and Wimmera fall within the rainfall controls specified earlier.

In addition to this, around Sale is a small wheat district in the wet region of Gippsland, and this is due to the low rainfall of a *rain-shadow*.

In the same way the rain-shadow to the south-west of Melbourne includes the drier coastal counties which grow wheat. In the Victorian Mallee, is a large extent of sandy loam country with a light winter rainfall from 10 to 15 inches. For a long period this land was deemed unfit for wheat, but experience has proved that it is quite profitable when properly worked on the *dry farming* 3-year rotation system of fallow, wheat, grazing There were 800 000 acres under wheat here in 1914.

In South Australia, there is a northward bulge in the isohyets caused by the Flinders Range and possibly influenced by the long gulfs running 200 miles into the continent. Here 6 counties around St Vincent Gulf each produced more than 2 million bushels for the season on 1915-16. The climate is ideal for wheat culture, nearly all the rain falling in winter. The 6-inch winter rainfall line seems to mark the outer line of wheat culture

OATS. — This grain only represents 5 % of the area under cultivation in Australia. Victoria has produced 55 % of the total, Tasmania is the next State, while South and West Australia are nearly as important. The distribution of the main crop differs considerably from that of wheat. The chief region is in the Central District around Melbourne, while the Wimmera region ranks next. Hence the temperature is 5° cooler than that for the chief wheat districts while the rainfall is heavier and the evaporation less. The whole of Victoria, — excluding the Mallee the mountainous districts east and Gippsland — is, however, very largely interested in the oat crop

In the other states, the limits are much the same as for wheat, save that a fair crop is grown along the cool wet south coast of New South Wales, where hardly any wheat is found. The most northern crop is in Queensland around Gayndah, where the average annual temperature is 70°.

SUGAR. – This crop is confined to the well watered east coast. The sugar is all derived from cane, apart from a little sugar beet grown in Victoria. The cane plantations extend down the east Queensland coast and into New South Wales.

The appending Table shows the climatic controls of the chief sugar cane fields. (See Table page 16).

In Queensland, sugar cane comprises ⅓ of the agriculture of the State (about the same as maize), and is worth more then 3 millions sterling annually. The plantations are confined to the narrow belt between the highlands and the sea. The rainfall is sufficient in most of the plantations, except in the Bundaberg and Ayr districts, where irrigation is practised. Cane-cutting is done chiefly in June and the followng cooler months.

In New South Wales, the sugar crop is less than 0.50 % of the total crops. It has been gradually driven north by fear of frost,and is now confined to the Grafton-Lismore region in the extreme north.

MAIZE. — About 93 % of the whole is grown in Queensland and New South Wales, in the littoral to the east of longitude 150°. Hence it re-

TABLE III. — *Climatic controls of chief sugar cane Fields at sugar sure.*

Latitude	Locality	Approximate Temperature	Annual Rainfall	Area of sugar 1917
16	Douglas	78 °F	83 inches	24 000 acres
17	Cairns	76	90	
17 1/2	Mourylian	76	159	34 000
18 1/2	Ingham	76	80	
19	Townsville	76	50	22 000
19 1/2	Ayr	75	45	
20 1/2	Proserpine	75	42	6 000
21	Mackay	72	68	42 000
24	Gladstone	71	41	600
25	Bundaberg	70	44	25 000
25 1/2	Childers	70	42	18 000
26 1/2	Maroochy	69	65	2 000
27 1/2	Rosewood, etc.	69	32	2 000
28	Nerany.	69	58	400
29	Lismore	68	70	11 000
30	Mac Lean	68	47	

quires for the best results a rainfall exceeding 25 inches and a temperature not less than that of Sydney (January 72° ; July 52°).

BARLEY. — South Australia and Victoria contribute 85 % of the total production. The crop is grown chiefly in the wetter and cooler portions of the wheat belt. In South Australia, Yorke's Peninsula and the Gämbier region are the chief centres; in Victoria, round Werribee; in New South Wales, in the Riverina.

VINEYARDS. — These are naturally confined to the well watered portions of the continent; South Australia and Victoria contain 80 % the vineyards. The localities lie between the 65°F and 55°F annual isotherms and (excluding irrigation settlement) are all between the 20 and 30-inch annual isohyets. Hence the climatic controls are very well marked.

POTATOES. — 80 % of the total crop is produced in the 3 States of Victoria (52 %), Tasmania (18 %) and New South Wales (12 %). In the last State the chief crop is grown on the slopes west of Bathurst and Goulburn and on the northern tableland and Glen Innes.

These regions all have about 30 inches of rain yearly.

9 - **Effect of the Weather on Crops in Alaska in 1918.**— GEORGESON, C. C., in *Report of the Alaska Agricultural Experiment Stations*, 1918, pp. 7-8, Washington, 1920.

The weather conditions play an important part in the operations of the Alaska farmer as the country is so close to the borderland of possibilities that a little shifting of temperature and rainfall may have a distinct influence on the final results as regards yield.

Nevertheless, the prevailing conditions are not so discouraging as might be expected at first sight considering the geographical situation.

During 20 years the crops have never been completely killed off by frost in June or July, as sometimes happens very much farther south in Canadian territory, or even in North Dakota.

In any case, the season without frost is always very short, which engenders the necessity of cultivation of grain crops which ripen very early and before the arrival of the autumn frosts. During the six years that an experiment station was in working order in the Copper River Valley, a fatal frost occurred about the middle of August every year, and grain that had not matured in time was fit only for hay.

The season of 1918 suffered a very severe winter, accompanied by a heavy snowfall which averaged more than 4 feet in depth in the Yukon and Tanana valleys. The total snowfall was between 5 and 6 feet. This was followed by a very late cold spring which made the sowing time 2 weeks later than normal. This is always a serious drawback in the case of grain crops, as the growing season must be correspondingly prolonged in the autumn to permit them to mature. The late spring was followed by a hot dry early summer. Wherever there was moisture enough in the soil, the growth was rapid for a time, but the grain was invariably stunted, and some of the late-sown seed especially in the Tanana valley, did not have moisture enough to start growth and therefore laid dormant until the rains came late in the summer. The result as a whole was short straw and a comparatively light yield.

Frost did not occur, however, until August 26 and 27, and fatal frost did not occur until the first week in September.

10 - Effect of Temperature upon the Polar and Altimetric Limits of Tree Growth.

— KOPPER, W., in the *Meteorologische Zeitschrift*, Vol. XXXVII, Parts 1-2, pp. 39-42. Brunswick, February, 1920.

There are certain regions of the globe where, either on account of the low temperature or the prevailing dryness, no trees can grow. Certain limits of cold and "aridity", however, can be passed by direct means, such as irrigation, artificial reduction of evaporation, protective measures against cold, etc., or by indirect means, e. g., defending a species from the competition of others more adapted to the climate and which if given full liberty of propagation would entirely suppress the weather plant and oust it from the limits of the zone. Protection against wind is of considerable importance in this connection; as is also the duration of the vegetative period.

In the present paper, the author studies the cold limit from the points of view of latitude and altitude.

The action of temperature upon metabolism is so complicated that it cannot be expressed by means of a simple formula, or by exact meteorological values, all the more, seeing that most stations and observatories possess no data on the temperature of the soil and on the amount of radiation.

On the other hand, the influence of meteorological factors is so important that even the study of the connection between the temperature of the air, the different phases of plant development, and the distribution of groups that have been determined systematically and physiologically, suffices to reveal many interesting correlations.

Such a correlaton is found between the isotherm 10° C. of the warmest month, and the polar limit of tree growth, the 2 curves coinciding almost completely. Sust'as in average and high latitudes, the mean temperature of the air is higher on the continents and inland than it is on the coast, so in like manner, the polar tree limit extends further towards the pole and attains higher altitudes in a continental, than a maritime climate.

Trees have been observed to cross the thermal limit of 9° C (for the hottest month in the year) in two districts, i. e., the Central Alps and Cape Horn.

From the Rigi and the Säntis, as far as the Upper Engadine, the tree limit rises by 550 m. (from 1745 to 2300 m.), whereas the July isotherm of 10°C. only rises 230 m. (from 1760 m. to 1990); in the Upper Engadine, the temperature of the hottest month is only 8° C.

Similar conditions exist in the region of Cape Horn: near the Beagle Channel trees grow up to 600 m. at places where the temperature of the warmest month cannot exceed 6° to 7°C.

On the other hand, there are places with a temperature during the warmest month it 10° C. or even more, where no trees will grow. This is the case in the Orkney and Shetland Islands, though the August temperatures there are 11°6 and 12.2°C., respectively. The Scottish Highlands are very poor in trees, and the limit of tree growth is reached at between 600 and 810 m. with July temperatues of 10°5 C. and 9° C, respectively.

It is an interesting fact that the Falkland Isles (February 9.6° C). unlike ,Tierra del Fuego, are completely bare of trees, and that the Faroe Islands (July, 10.8° C), even trees which are artificially planted and receive every care, take root with difficulty . It would be well to make acclimatisation experiments there, with the strong varieties of beech growing at Cape Horn.

11 - **The Spring Awakening of Arable Land.** — LUMIÈRE, A., in the *Comptes rendus de l'Académie des Sciences*, Vol. CLXXI, No. 18, pp. 868-871. Paris, November 2, 1920.

In the temperate zones, the arable land awakens at the end of winter to greater activity, which is chiefly shown by the germination of the seeds it contains, and by the recrudescence of nitrification in the soil.

Putting aside the suggestion advanced by MÜNTZ and GAUDECHON, that this re-awakening of the land in spring is due to the atavism of the micro-organisms (1), the author has sought to discover another cause of this seasonal rhythm, and has put forward the hypothesis that an important part in the phenomenon in question is played by the toxic products secreted by the roots of plants, or resulting from the transformation of plant remains after the fall of the leaves and the death of annual species, for a certain time is needed before these toxic products can be destroyed by fermentation or oxidation, or can be diluted or removed by rain.

---

(1) See, *R.*, Nov. 1913, No. 1241. (*Ed*).

This idea has been confirmed by the following experiment :— A sample of garden soil that had been under cultivation during the preceding summer, was taken by the author in November. This homogenous sample was divided into 2 similar portions, one of which was repeatedly washed with distilled water in order to remove most of the soluble matter present in it, while the other was simply watered with similar distilled water. At the laboratory temperature, the small plants that usually appear in spring, began to grow with great rapidity after a few days upon the surface of the washed soil sample, whereas the unwashed sample, although liberally watered, remained sterile. The washing had removed all the substances that prevented the germination of the seeds.

By extracting systematically the toxic matter in 10 kg., of the same soil, and then evaporating the washing water at a low temperature until reduced to 1 litre, the author obtained a reddish solution containing a total of 28 gm., of total solids. When this solution was used for watering, it absolutely prevented all germination, no matter what soil was selected or what the season might be.

Seeds soaked in this extract for some days did not lose their power of germinating, provided the extracts products, which did not seem to be actual toxins but merely inhibitory agents, were removed by thorough rinsing

The bodies preventing the germination of the seeds are not destroyed or even altered by heating them at 130° C. for half an hour in an autoclave, and would thus seem to be composed neither of toxins nor diastases.

The author is continuing his experiments, with a view to devising some simple and practical methods of either saturating or destroying these substances, as by this means it would be possible to improve, within considerable limits, the economic conditions of crops.

12 - The Phosphoric Acid in Sandy Humiferous Soils and in Their Solutions. —

BRIOUX, CH. (Directeur de la Station agronomique de la Seine-Inferieure Rouen, France) in the *Annales de la Science Agronomique*, Series 6, 1920, pp 80-86 Paris, 1920.

In normal, non-acid soils with an average humus content, the phosphoric acid is usually present in the form of tribasic calcium phosphate associated with a small quantity of iron phosphate and alumina ; a third part is combined with the black matter of the soil, and as a result of nitrification, is gradually placed at the disposal of the plants in a much divided form that is easily assimilated. On the other hand, the water surrounding the soil particles normally dissolves but very little of the phosphates, so that, as a rule, the solutions circulating in the soil and providing the plants with food, only contain some tenth parts of a milligramme of P_2O_5 per litre, and rarely more than 1 to 2 mgm., even when the soil is very fertile ; but the experiments of Th. SCHLOESING have demonstrated that these small quantities, which are continually renewed, are sufficient to ensure the complete development of maize grown in nutritive solutions.

The phosphoric-acid content of soil solutions is constant for any given soil, and M. DUMONT explains its variations in different soils by the variable composition of the humates and humo-phosphates present in them.

This suggestion seems to be borne ont by the experimental results obtained by the author, showing that the high P_2O_5 content of the solutions of certain soils is connected with the presence of a large amount of humic matters together with a deficiency in lime

These experiments were carried out upon humiferous, sandy soils composed of a coarse sand consisting entirely of silica, and which were originally yellowish, but from repeated manuring, had assumed the blackish hue characterising humiferous soils. They had an acid reaction, and were very poor in potassium and lime, and very rich in P_2O_5.

From his experiments, the author draws the following conclusions :—

In the case of sandy, humiferous soils without lime, the phosphoric-acid content of the soil solution appears to depend upon 3 factors, which are, in descending order :— (1) Lime content ; (2) amount of black matter ; (3) total phosphoric-acid content.

As soon as the lime content falls below 2 per 1000, the humo-phosphates can begin to dissolve to a noticeable extent in the water surrounding the soil particles.

Sandy humiferous soils enriched by very intensive cultivation are capable of giving solutions containing far more phosphoric acid than is generally recognised, and certain losses of black matter and of phosphoric acid may be due to the action of drainage water.

In order to derive most advantage from such soils, the first thing to do is to add lime, which will precipitate the humus more thoroughly, on the particles of sand and will give more stability to the phosphatic compounds. The lime will also promote nitrification and facilitate the double decompositions taking place between the fertilisers and the soil. It is equally necessary to add potash which is usually lacking in this type of soil.

Quick or slaked lime would be too violent in its action, and is best replaced by lime compost and, when possible, by soft chalky lime, more or less finely pounded, as its chemical action is in direct proportion to its fineness. The author obtained excellent results by adding to these sandy, humiferous soils 2000 kg., of pulverised chalk refuse per hectare, together with potassic fertilisers.

13 – **Copper in the Soil and in Plants.**— MAQUENNE, L., and DEMOUSSY, E. (*Bull. Soc. Chim.* p. 266, 1920), in *L'Industrie Chimique*, Year VII, No. 68, pp. 243-244. Paris, 1920 (1).

The presence of copper in the plant organism, first regarded as accidental, was recognised later as a normal occurrence. Now, however, it can be said that copper probably exists in all plants, for none of those examined so far have been found free from this metal.

The authors have found copper everywhere in the soil, but in very varying amounts. The result of their experiments is given in the following table, the average quantity of copper present being expressed in mgm. per kg., of soil, and the number of experiments being given in brackets: —

---

(1) See *R.*. 1919, No. 568, and *R.*, 1920, 630. (*Ed.*)

	Mgm. per kg.
Aveyron high arable land (5)	2
Finistere, various crops, sandy heaths (landes) 10	20
Ille-et-Vilaine, garden soil, 52 Briac (1)	7
Seine-et-Oise, farm crop (5)	5
Lower Seine, pasture, various crops (11)	12
Yonne, soils under wheat and leguminoseae (9)	3
Brazilian soil, Santa Cruz (1)	25
Japanese soil (1)	10

Some exceptional soils show a considerable deviation in their copper content from the preceding averages. Thus, in the Department of Eure-et-Loire, 3 samples of soil were found with the copper content of 14, 19 and 30 mgm., per kg., respectively.

The soils of vineyards yielded the following figures: — 107 mgm., in the case of a vineyard in Herault that had been sulphated for 12 years; 43 mgm., in that of a vineyard sulphated from 1882 to 1915, but not since; 15 mgm., in the case of an unsulphated vineyard; a sulphated vineyard at Aigues-Mortes, in Clos-Lombard, 60 mgm.; a sulphated vineyard in Clos du Puits 30 mgm.; sulphated vineyards at Jarras 150 mgm.; uncultivated soil, 2 mgm.

The examination of these figures shows that very large quantities of copper are sometimes found in the soil of sulphated vineyards, the superficial layers containing as much as 200 to 300 kg., of copper per hectare. The metal is retained by the fine particles of the soil owing to their absorbant properties, and also by the chemical reactions in which they may be involved, so that the drainage water is only able to remove an infinitesimal amount. Vineyard soils thus become constantly richer in copper; their quality, however, does not vary, for they fix it with such energy that the plants are not able to assimilate too much,

What relations can be supposed to exist between copper and plants? The universal presence of the metal in the soil explains why it always occurs in plants. The authors have studied its distribution in the different organs of the same plant, and have reached the following conclusions: —

Copper is met with in all parts of the plant, which proves its great mobility. This power of migration can only belong to a substance that is soluble in the cell sap; this is, in fact, the case with copper.

It has been found that the copper is transported by preference to those parts where vital activity is greatest or about to become most intense. When the fruits are approaching maturity, the copper can be shown to move definitely towards them. The fall of the fruits is evidently one method of eliminating the copper absorbed by the plant during its active life.

Copper, in the right proportions, must be regarded as an essentially migratory element which travels about the plant at the same time and in the same manner as the nutritive principles, without in any way harming the tissues through which it passes. It may even be of use to them.

14 - **An Experience in Crop Production.** — JORDAN, W., H. and CHURCHILL, G.W. in the *New York Agricultural Experiment Station Bulletin* No. 465, pp. 1-20. Geneva, N. Y., June, 1919.

The experience covers 17 years of observations, 1896 to 1913, and the data given may be regarded as a report of progress. The experiment was extended over 4 years of rotations of 4 years each, the crops being maize, oats, wheat, barley and grass, in the order named, with the exception that 2 crops of maize were grown in succession during the first two years. The area of the field selected was 12 acres, and the 8 plats into which this was divided each covered 1 ½ acres. On 4 of the plats, with the 4 methods of treament, clover was included in the rotation, and in the other 4, receiving entirely similar treatment, timothy was included.

The points concerning which conclusions more or less definite may be drawn are as follows:

I. RELATIVE YIELD OF THE SEVERAL PLATS UNDER TREATMENT WITH: 1) FARMYARD MANURE; 2) COMPLETE COMMERCIAL FERTILISER AND 3) ACID PHOSPHATE, SUPPLEMENTED BY A SMALL APPLICATION OF SODIUM NITRATE. — The largest yield of crops, measured in terms of dry matter was with farmyard manure. Both this and the commercial fertiliser produced aproximately 56 % more dry matter than the plats receiving no fertiliser. The plats receiving phosphoric acid with partial nitrogen and no potash produced about 33 % more than untreated plats. In considering these figures, it should be kept in mind that the crops were produced under a system of rapid rotation, and also in 1910 all the plats had received 1 ton of burned lime per acre, previously slaked. The following Table shows the relative productivity of the several crops entering into the experiment :—

Yield of dry substance under the several methods of treatment
Area of each plat = 4 rods × 60 rods.

Treatment		Maize	Oats	Wheat	Barley	Hay	Total
		lb.	lb.	lb.	lb.	lb.	lb.
With clover in rotation	Farm Manure	48 659.9	17 036.3	20 636.5	4 973.3	27 061.8	**118 367.8**
	No fertiliser	32 998.1	12 422.4	9 059.8	3 555.1	14 818.4	**72 853.8**
	Partial fertiliser	41 273.0	17 184.7	15 563.5	4 381.1	21 689.6	**100 091.8**
	Complete »	45 442.5	19 451.0	20 418.9	4 882.0	23 722.8	**113 917.2**
With timothy in rotation	Farm Manure	42 932.0	17 898.2	19 311.8	4 206.1	25 211.4	**109 559.8**
	No fertiliser	34 615.2	12 812.8	9 198.0	3 343.4	20.649.6	**70 169.9**
	Partial fertiliser	40 731.6	14 941.2	14 727.4	3 670.7	14 921.5	**88 932.4**
	Complete »	50 489,0	17 191.3	17 251.5	5 013.0	16 353.1	**106 297.9**
	Total . . .	**337 141.6**	**128 937.9**	**126 168.3**	**33 964.7**	**164 428.2**	

The fact should be noted that the growth of dry substance in maize is over twice that in either oats or wheat, (counting the yield of barley as part of the wheat), or even of hay in spite of the fact that the crops of the cereal grains and hay were considered very satisfactory

The production of dry matter with the farmyard manure and complete commercial fertiliser was in the proportion of 118.3 for the former to 113.9 for the latter: If allowance is made for the difference in yield of hay due to the fact that timothy sod was maintained for only one year (it is a well known fact that more is necessary to obtain the maximum results) and comparison is made of the cereal crops produced, the relation of farmyard manure to commercial fertiliser is 91 to 90 with clover in the rotation, and 84 to 89 with timothy.

II. INFLUENCE OF CLOVER AS A FACTOR IN FERTILITY. — A comparison between the clover and timothy plats shows that in the 17 years there were produced of all crops, 29800 lb., more of dry matter on the former than on the latter. If, however, the comparison is made on the basis of the cereal crops, the difference in favour of clover is 13.500 lb., of drymatter.

These results indicate considerable advantage from the use of clover.

However a study of the yield of dry matter on the plats receiving no fertiliser, one with clover in rotation and the other with timothy, shows that production was maintained on the latter as efficiently as on the clover plats. The yields following the first rotation were maintained without any essential drop.

III. SOIL ANALYSIS AS A MEANS OF MEASURING FERTILITY. — A comparison of the analyses of the soil on the several plats before and after 17 years cropping showed no differences or changes which gave either any indication of the effect of the dissimilar systems of treatment or of the variation in productivity of the plats at the end of the 17 years.

IV. RELATIVE PROFITS. — From the figures tabulated with regard to the cost of fertilisers and the value of the crops, it is evident that the cheapest increase of production was secured by the use of acid phosphate, supplemented by a small proportion of sodium nitrate. Whether or not the increased yield from the use of the complete fertiliser with a maximum amount of nitrogen would be profitable would depend upon circumstances.

The experiment has since 1914 been conducted in new lines ; — the authors outline the general scheme.

15 - **The Necessity of a Change in Crop System in Canada and the Choice of Crops and Soil Productiveness.** — CUTLER, G. H., in *The Canadian Power Farmer*, Vol. XXV, No. 10, p. 18. Winnipeg, Oct 1920.

Reports indicate that in Western Canada, owing to the inroads of weeds, soil drifting and consequent increasing difficulties in the conservation of moisture, the former profitable crop yields cannot be maintained.

The underlying causes of the losses are considered to be due :—

(1) To the prevalent single cropping system, which results in multiplication and distribution of weeds, and in rapid reduction of organic matter in the soil;

(2) To the effects of blowing soil.

The author advocates the advisability of a wider choice of crops on systematic rotation and the use of grasses and legumes in conjunction with the cereals. Winter rye grass (*Lolium*) sweet clover (*Melilotus alba*) and sunflower crops would alleviate problems in soil productiveness. This acts as a pasture crop in autumn and spring, a protective crop against ground sweeps and soil blowing, a trap crop for snow and a fibre crop when used as summer pasture. Awnless brome grass (*Bromus inermis*) western rye grass and timothy (*Phleum* sp.), in conjunction with the aforementioned crops, will aid in the definite control of weeds and soil drifting.

Where there is limited rainfall and these conditions also prevail, the application of the outlined methods would be practically impossible and entirely impracticable. Extensive reclamation experiments are advocated in this case in order to utilise these large tracts for grazing.

16 – **The Value of Farmyard Manure on Utah Soils.** — HARRIS, F. S. in *Bulletin* No. 172. *Utah Agricultural College Experiment Station*, pp. 3-21. Table XIV, Figs, 12. Logan, Utah, March 1920.

A report of experiments on the value of farmyard manure in increasing the yield of various crops: 1) On irrigated land; 2) On dry farm soils. In the first case the trials were conducted on a deep rather fertile limestone soil at an irrigated farm at Greenville, but the dry farming experiments were carried out on clay loam soil at Nephi. Details are given as to the exact chemical composition of these soils etc.

RESULTS 1 IRRIGATED. — *With sugar beets.* — The following Table shows the average yields for the years 1918 and 1919 for the 5 ton, the 15 ton and 40 ton applications and for the years 1916 to 1919 for the other applications: —

Manure addet		Yield (Tons per Acre)		Increase due to manure		Increase in tons of beets for each ton of manure
		Roots	Tops	Roots	Tops	
Nil	. . . .	6.27	4.51	—	—	—
5	Tons	16.01	7.71	9.74	3.23	1.948
10	»	18.03	7.01	11.76	2.50	1.176
15	»	19.22	9.31	12.95	4.80	0.863
30	»	20.40	10.25	14.22	5.74	0.474
40	»	22.13	14.04	15.86	10.43	0.397

The increase per ton of manure is greater with the lower application and gradually decreases as the quantity of manure increases.

Potatoes. — A comparison between the results obtained on an unmanured plat and on a plat manured at the rate of about 10 tons per acre each year (1912-1919) showed that the average yield in bushels per acre was 150.8 on unmanured to 254.8 on manured, and the average increase in yield due to the manure was 104 bus.

A further experiment indicated that when manured at the rate of 5 tons per acre, the yield was increased by nearly 13 bus., per ton of manure, but when 40 tons were applied, the increase was only 4.3 bus., per ton.

Wheat. — An increase in yield was noted at the rate of 2.00, 1.13 and 0.33 bus. of grain respectively for each ton of manure when 5,15 and 40 tons of manure per acre were applied.

Oats. — An increase was noted at the rate of 1.65, 1.21 and 0.36 bus of grain respectively for each ton of manure when 5,15 and 40 tons per acre were applied.

Maize and stover. — The average of nine years of manure applied to maize gave an increase of 3.83 bus , of grain and 428 lb. of stover, and 1.61 bus., of grain and 214 lb., of stover respectively for each ton of manure when 5 and 15 tons were applied to the land each year.

RESULTS II : UNDER DRY FARMING. — The data with regard to the yield of Turkey Red wheat as affected by manure under dry farming during five years, indicate that although the returns are not so immediate as under irrigation there was however a distinct increase of 3.3. bus., per acre when 10 tons each alternate year were applied. The same average increase during 5 years was noted where 15 tons of manure were applied only at the beginning.

These results counteract the former popular idea that manure is of no value on the dry farm. On account of the low moisture content of the soil, the manure naturally decays slowly, but the returns will no doubt come in during later years.

17 - **The Utilisation of *Opuntia* spp. as Green Manure.** — See No. 59 of this *Review.*

18 - **The Industrial Utilisation of the Locust.** — SCHUGURENSKY, L., in the *Revista de Centro Estudiantes de Agronomia y Veterinaria de la Universidad de Buenos Aires*, Year XIII, No. 99, pp. 13-17. Buenos-Aires, April, 1920.

By means of analytical data and methods for extracting the fats and making concentrated cattle-foods and manure from locusts (1), the quantities of these insects which could be utilised in this way in the Argentine Republic can be estimated. According to statistics of the " Defensa Agricola ", season of 1916-1918, the number of locusts killed in the whole of Argentine, according to their different stages of development, was as follows :—

« Mosquita » (Newly hatched)		« Saltona » (Not yet able to fly)		« Voladora » (Adults)	
kg.	Hectares	kg.	Hectares	kg.	Hectares
38 410 521	138 717	371 715 227	289 865	439 951	6296

---

(1) See *R.*, June, 1919, No. 690. (*Ed*)

The most interesting fact is that the largest number killed was in the coastal area, which would greatly facilitate transport for industrial use. This may be seen in the following Table:—

District	« Mosquita »	« Saltona »	« Voladora »
	Kg.	Kg.	Kg.
Buenos Aires	39 900	64 101 326	34 908
Santa Fé	976 370	53 734 311	—
Corrientes	1 944 900	21 005 700	118 748
Entre Ríos	3 896 185	63 359 850	95 772
Córdoba	17 355 549	74 345 704	165 428
Pampa	322 517	12 674 959	
Total . . .	—	**289 221 850**	

During the three years in question, an average of 96 000 metric tons of saltona locusts was killed yearly. Of this amount 30 000 metric tons was utilised, bringing in a profit of nearly 100 000 gold pesos (£240 000 at par) from the products obtained; the cost of the first works and of the preparation appear not to be very high.

19 – **Phosphates of Lime in North Africa (Barbary).** — JOLEAUD, L., Les richesses minières de l'Afrique du Nord (Maroc, Algerie, Tunisie), in the *Bulletin de la Société d'Encouragement pour l'Industrie Nationale*, Year CXIX, Vol. CXXXII, No. 4, pp 125-130 + figs. 2-5, 1 map. Paris, 1920 (1).

Certain of the Algerian and Tunisian phosphate deposits are localised north of the Sahara and south of the High Plateaux, at Gafsa, Tébessa, and in central Tunisia, whilst others are found north of the High Plateaux, at Tocqueville, and at Bordj-Reddir, all in Eastern Algeria and in the Regency. This is because the Algeria,, "horst", which emerged like the Sahara desert, at the period when the phosphates were formed, stretches from the Province of Constantine, where it is not extensive, takes on a considerable development to the south of Algiers, especially towards Oran, whence the name sometimes applied to it, "the Meseta of Oran", in comparison with the central plateau of the Iberian Peninsula.

This great stretch of tableland is interrupted in Western Morocco by the Middle Atlas Mountains and, as was to be expected, discoveries of phosphates have recently been made on the edges of this chain.

In the Atlantic Moghreb, west of the Middle Atlas, there is a meseta corresponding to that of Oran, called the Moroccan meseta, which embraces the countries of Zaïan, Zaer, Zemmour, Chaouia, Doukkala and Abda. Similarly, there are phosphatic formations between El-Boroudj and Oued-Zem, lying between the Moroccan meseta and the Upper Atlas Mountains. Perhaps in the future these beds also will be found to extend over larger areas on the borders of the Middle Atlas Mountains.

---

(1) See *R.*, 1919, Nos. 827 and 829. (*Ed.*)

The formation of phosphate of lime in the shallower seas has been revealed by deep-sea dredging.

The facts stated above give an accurate account of the geographical conditions existing when the phosphatic deposits in North Africa were formed. At the beginning of the tertiary period, during the eocene, the sea extended over vast areas of Barbary, where there were two zones of very different geographical character, viz:—

(1) The Riff and it's approaches, the Algerian Tell and North Tunisia, where phosphates are scanty or absent

(2) Around the Moroccan Chaouia, on the Numidian High Plateaux, in Aurès, and in Central and Southern Tunisia, the phosphates are generally rich.

In Southern Barbary, occupied by a sublittoral sea, phosphates accumulated in certain localities in concordance with the former topography of Barbary. The dislocations which had affected its subsoil at the end of the secondary periods, at the ultimate place of the cretaceous, gave rise to submarine or emergent prominences which in time formed stops in the path of the marine currents. The frequency which the remains of sharks and crocodiles are found in these phosphate beds can be explained by the attraction that the accumulation of large quantities of organic débris on these stops had for carnivorous animals. Even to-day these animals are to be found in great numbers behind the bars off the shores of eastern Africa. It is at these points, where the marine currents stop behind the bars, that, during the eocene period, the remains of living creatures accumulated and formed nodules of phosphate of lime in consequence of a series of chemical reactions. By its decomposition at the bottom of the sea, the organic matter produced ammonia, which, reacting on the phosphate of lime in solution in the salt water, produced ammonium phosphate. This phosphate, coming into contact with carbonate of lime, also in solution in the sea water, was transformed into phosphate of lime, the particles of which became centres of attraction for more particles of phosphate; these may result from combination between the ammonium phosphate and the carbonate of lime resulting in the action on the sea-shells of carbonic acid in solution in the water.

In Barbary, rich beds of phosphate are always found in the same soil and in the same stage of the eocene series. The physical conditions of the marine areas of North Africa during the lower eocene, can easily be deduced from the distribution of fossil remains of various genera of fish in the phosphate beds, viz:—

(1) In the rich beds of Djebel-Ouk, in the Southern Province of Constantine, in Metlaoni, Redeyef, Ain-Moularès, and in South Tunisia, those species which are usually found near the coasts are fairly common, whilst those from the open sea are rare

(2) In the relatively rich beds of the zone south of the High Plateaux, at Kouif, Dyr near Tébessa, in Constantine, Kalaat-ès-Senem, Kalaa-Djerda and in Central Tunisia, the littoral species are only occasionally found and those from the deep seas are no longer very rare.

(3) In the poorer phosphate beds north of the High Plateaux, at Tocqueville, Bordy-Reddir, and South of Sétif in West Constantine, there are no littoral species but deep-sea remains are common.

(4) In the calcareous regions of central Tell, on the slopes of the Constantine Region, where the phsphate content is below 30 %, and has an indisputable effect on the fertility of the arable land, very little fish remains are found, and those all belong to deep-sea species.

(5) In the non-phosphatic calcareous regions of the coastal chains sharks' teeth are not found.

A certain relation thus exists between the variations in the phosphate content and changes in the fossel fauna of the eocene period, and this can easily be shown by the study of the shark's teeth.

Such are the facts deduced by the author from a comparative study of all the phosphate deposits, of North Africa. With the aid of these results it is possible to define clearly the regions where this valuable mineral fertiliser could be found in Barbary. The author believes that all workable deposits in Algeria and Tunis are known, but that in Morocco, from the southern border of the meseta to the limits of the Sahara there is yet a great deal of exploration to be done.

20 - **The Potash Salts of Upper Alsace and Their Utilisation in Colonial Agriculture.** — CHEVALIER, A., in the *Bulletin agricole de l'Institut Scientifique de Saigon*, Year II, No. 10, pp 289-297. Saigon, Oct., 1920.

The author gives a summary of the following works: —

1) A. WEHRLIN, F. BINDER, E. BOUCAR, E. REMY, G. DE PLACE, "Les Mines de Potasse de la Haute-Alsace", 1 vol., pp. 98 (extracted from the *Bulletin de la Société industrielle de Mulhouse*), Mulhouse, 1912.

2) P. DE RETZ "Rapport sur le Bassin de Potasse d'Alsace". This work has not yet been published but the proofs were lent to the author.

A report on the Théodor Mine was added, in order to inform the French Colonies about one or more valuable fertilisers for colonial agriculture.

The author describes the history of the potash mines of upper Alsace, the geology of the basin, the reserves, present state of working, future prospects, sales, and the agricultural use of potassic fertilisers. As regards tropical agriculture, data on the quantities of potash to apply per hectare for the chief crops are lacking.

The form under which the potash should be exported to the Colonies also requires to be ascertained. It should be remembered that natural powdered sylvinit as usually sold contains only 20-22 % of potash (K_2O). A crop, therefore, which requires 100 kg., of potash per hectare should receive nearly 500 kg., of the natural Alsatiam fertiliser. Pure potassium chloride only represents 63 % of potash.

In order to diminish freight charges, the author recommends the American method of importing concentrated potassium chloride of 90 per cent. purity, thus eliminating a large part of the sodium chloride ordinarily present in natural potash salts. All the Alsatian mines possess the necessary plant to do this. The potash salts as extracted from the mines are somewhat hygroscepic, and in damp tropical climates there is a risk of losing part of the pulverised fertiliser through the sacks.

Before the war the Union des Sociétés d'engrais potassiques at Stassfurt had commenced demonstrations in various parts of the world to show the utility of this fertiliser for tropical countries, but this was stopped during the war.

Most tropical crops, much more exhausting than crops of temperate regions, certainly require a far larger proportion of potash than crops in Europe.

It is high time that the scientific study of this subject should be taken in hand. Up to the present, the colonial use of fertilisers in the Colonies has been quite empirical.

The need for using artificial manures in colonial farming is increased by the scarcity in many countries of domestic animals capable of supplying natural manure and by the absence of cakes which could return to the soil some of the elements absorbed by the crops.

Alsatian potassium chloride is therefore called upon to render the greatest service to the colonies in developing all tropical crops and as these extend and improve so will it become necessary to import those fertilisers which are lacking in the colonies in increasing amounts

21 – **The Dynamics of a Fluctuating Growth Rate.** — REED H. S. (Graduate School of Tropical Agriculture and Citrus Experiment Station, University of California), in the *Proceedings of the National Academy of Sciences of the United States of America*, Vol. 6, No. 7, pp. 397-415, Figs. 3, bibliogr of 3 works. Easton, Pa., July, 1920.

The quantitative study of the growth rate of shoots on a perennial plant was attempted in order to gain an insight into some kinetic aspects of the problem of growth. Measurements were taken of 70 selected shoots of " Royal " Apricot Trees which had been growing for two years in the orchards of the Citrus Experiment Station at Riverside, California. The observations were made during the growing season of 1918.

The growth of shoots was found to follow a definite though fluctuating rate. Analysis indicated that the seasonal growth consists of 3 distinct cycles of approximately 9 weeks each. The growth impelling agency was at the maximum at the beginning of the season and diminished as growth proceeded. In the first 7 or 8 weeks the rate declined more rapidly than in any other period. From the 8th to the 19th week it was fairly constant, only diminishing about 2.5 cm., and from then onwards the decline was considerably more rapid. At the end of the growing season the rate was less than $^1/_{10}$ of the initial rate. The growth in each cycle closely resembled the rate of an autocatalytic reaction and for the entire season it conformed to that of a reaction consisting of two unimolecular reactions one of which at first accelerated and subsequently retarded the other.

The author states that if growth be assumed to be proportional to the amount of active catalyst present, a method is available for studying the dynamics of the growth process.

22 – **The Influence of Cold in Stimulating the Growth of Plants.** — COVILLE, F. V. (Smithsonian Institution, U. S. National Museum, Washington D. C.), in the *Proceedings of the National Academy of Sciences of the United States of America*, Vol. 6. No. 7, pp. 434-435. Easton, Pa, July, 1920.

The author gives contradictory evidence to the general belief that native trees and shrubs become dormant because of the cold, and that warm weather is in itself the sufficient cause of the beginning of new growth in spring.

Dormant trees and shrubs which had had two or three months of chilling, either outside or in artificial cold storage, started into growth in the normal manner in the spring, but if kept warm all the winter they did not start into growth at the usual time but continued their dormant condition for weeks and months, and sometimes for a whole year. When finally growth commenced it was of an abnormal character. One of these, dormant plants was found to be readily started into healthy growth even after a year, by subjecting it to a period of chilling. The best temperature for chilling was 32° to 40° F., applied either in light or darkness. By subjecting one part of a dormant bush to a chilling temperature and keeping another part of it warm, the chilled portion was brought into full leaf and flower while the other part remained completely dormant.

During the process of chilling, the starch stored in the cellars is transformed into sugar and this is necessary before the plant can utilise its store of starch in making spring growth. If warmth alone would start growth, the stored food required by the plant for its normal vigorous growth the following spring would be wasted in a burst of new autumn growth, which would be killed by the first heavy frosts and cause ensuing weakness and probable death.

Further investigations are urged, especially in the determination of the proper temperatures for the storage of different kinds of seeds, bulbs, cuttings and grafting wood ; for the treatment of plants which are to be forced from dormancy to growth at unusual seasons, and for the storage of nursery stock so that the nurseryman may have plants in proper condition for shipment at any date.

23 - **The Influence of Nutrition and Root Activity Upon the Collapse and Desiccation Produced by Cold.** — PANTANELLI, E, in the *Resoconti della Reale Accademia dei Lincei*, Vol. XXIX, Series 5, Parts 1-2, pp. 66-71. Rome, 1920.

Continuing his researches on the effect of low temperatures upon plants, the author has carried out a series of experiments in order to determine whether the condition of the root system has any influence upon these phenomena, and if so, to what extent.

If the temperature of an organ is reduced to near freezing point, an increasing permeability of the cell is brought about. This shows itself by the rapid emission of water from a tissue that has been kept dry, and by the exosmosis of substances from a tissue immersed in water.

The fact is general: an examination, with the naked eye or a microscope of plant organs, and especially of thin leaves, reveals the fact that during great lowering of temperature the cells contract, their contents being ejected into the intercellular spaces: the loss of turgescence is shown outwardly by wilting.

In order that turgescence be restored with the elevation of the temperature, it is necessary that the water which has been expelled into the intercellular spaces, should be re-absorbed by the cells. This cannot take place, should the water have evaporated either during the lowering of the temperature, or as a result of raising it. In this case, the evaporated water must be replaced by root action, otherwise the organ will wither definitively, although it has not been killed by the cold.

The state of the roots is thus of the greatest importance in re-establishing turgescence, if the organ is to repair the injury caused by the cold.

(1) The renewal of root activity after cooling is rapid in proportion to the injury the root system has suffered and as the soil regains its warmth more quickly. It has been found that the acidity of the soil and a liberal supply of phosphates, render the roots more resistant to cold, whereas the alkalinity of the soil and a generous application of nitrogen make them more susceptible to it.

In the first case, the roots begin to work as soon as the temperature rises, in the second they are a long time in functioning, so that the transpiration organs wilt completely and all the more rapidly, the more the permeability of the cells of these organs has been increased by the lowering of the temperature.

(2) In a second series of experiments, the author studied the effect of soil moisture upon resistance to cold, and subsequent recovery of aerial organs. For this purpose pot cultures were watered with different quantities of water, so that the moisture of the soil was maintained approximately at 5, 10, 20, 40 and 60 % (as compared with soil dried at 100°C.). At the moment of placing the plants in the refrigerator, these moisture percentages were carefully determined. During cooling, those parts of the aerial organs suffered most which were richest in water, but with the rise of the temperature to 15° C., the parts that had least suffered at once began to transpire again, even before the roots had re-commenced to function. Thus, in soil that was too dry, just as in soil with too high a water content, the plants received a insufficient supply of water and withered. This was more striking in the case of the haricot then in that of the chick pea, for as the aerial portions of the former resist cold better than those of the latter, they begin to transpire again more quickly as soon as the temperature is raised.

(3) It is not, however, enough for the root to regain its absorbent activity in order to restore the turgescence of the aerial organs after thawing. It is necessary that the water should rise from the roots to the stem and thence to the leaves, and as it is the living cells that pump the water into the wood-vessels, it is of interest to ascertain how much the interference in the conducting function has to do with the total injury to the plant.

In order to determine this, the author placed in the refrigerator entire plants of garden beans, 60 cm., in height, that had been grown in nutritive solutions, or only the stalks or even tips of the stems placed in the same solution, or in spring water.

The detached tips suffered less than the entire plants, because they absorbed water more easily after the temperature was raised. The stems cut at the root-collar suffered more than whole plants, since the water had to travel a long distance without the assistance of root-pressure, and because the cells that cause the ascension of the sap had suffered from the cold.

Encouraged by these results, the author limited the action of the cold to one part of the plant, by affixing small glass receptacles filled with a freezing mixture to the root, part of the aerial organs, or to a portion of the stem without detaching it from the rest. When only the aerial portions were subjected to the action of cold, they did not lose their turgescence until the temperature had fallen lower than that which sufficed to render them flaccid when the roots were also treated, whereas it was enough to cool down the soil, that is to say the roots, in order for the stems to lose their turgescence at a temperature which was much higher than that which affected the entire plant. If the stems alone were subjected to the action of cold, they quickly regained their turgescence as soon as the temperature was raised (unless the temperature had been lowered to the fatal point), whereas if the roots had also been affected by freezing, the stems remained flaccid for some hours, or even longer, and if the roots alone had been treated, the effect was irreversible, and the stems withered.

All these experiments prove that root activity is a most important factor in determining the resistance of a plant to cold. Further, since the actual damage caused by cold is greater, the longer the part takes to regain its normal turgescence after the temperature is again raised, it is evident that the activity of the root plays an essential part in the restoration of the function of the aerial organs.

24 - **Respiration of Cereal Plants and Grains. — I. Of Sprouted Wheat; — II. Of Rice Paddy and Milled Rice; — III. Of Frosted Wheat Plants; — IV. Of Wheat Plants Infected with Stem Rust.** — BAILEY, C. H. and GURJAR, A. M. (Division of Agricultural Biochemistry, Minnesota Agricultural Experiment Station, St. Paul), in *The Journal of Biological Chemistry*, Vol. XLIV, No. 1, pp. 5-18, figs. 2, tables 6. Baltimore, Md., Oct., 1920.

Results of investigations in connection with the respiration of stored wheat have already been published (1).

I. — Attention was duly directed to determine the effect of sprouting upon the respiration of the grain, to ascertain whether or not this form of unsoundness on bulk grain could be expected to affect its keeping qualities.

A chemical analysis of the samples tested under varying conditions showed the normal wheat to contain 0.16 % of reducing sugars (calculated as dextrose), while the samples germinated 24 and 48 hours respectively, contained 0.59 % and 1.11 % respectively, — the ratios being 14.4 : 53.2 : 100 in the order named.

The graph and the Table establish the fact that respiration, and consequently the quantity of heat energy released per unit of time and material, proceeds at a higher rate in sprouted grain than in normal wheat. This should be of significance in commercial storage of bulk cereals, and in grading grain when the system employed takes note of the respiration and keeping qualities in storage.

Normal		Sprouted 24 hrs		Sprouted 48 hrs	
Moisture	CO₂ respired per 100 gm of dry matter in each 24 hrs	Moisture	CO₂ respired per 100 gm of dry matter in each 24 hrs		CO₂ respired per 100 gm. of dry matter in each 24 hrs
per cent	mg	per cent	mg	per cent	mg.
11.39	0.216	12.19	0.615	12.10	1.950
12.27	0.255	13.26	1.451	13.14	4.010
13.24	0.320	14.36	3.580	13.28	7.032

15.33	3.660	16.01	24.270	—	—
15.94	7.320	—	—	—	—

II — A series of samples representing rice paddy and its milled products at different stages of milling were secured in order to test the hypothesis that respiration was most active in the germ or embryo, and lowest in the endosperm. A comparison was made between the respiration of the rough rice or paddy and that of the rice from the "stone" and the "huller".

The treatment accorded them and the method employed were similar to those employed in the wheat studies previously reported (1). The graphs and Tables indicate plainly that the paddy respires much more vigorously than milled rice, and as milling proceeds the rate of respiration diminishes. Thus, the rice from the stones respires approximately 0.6 and that of the huller about 0.3 times as vigorously as the paddy.

The results of this study appear to support former evidence with regard to the seat of the most active respiration in a typical grain. It also shows that with different cereals, the relative acceleration of respiration with an increase in the moisture content of the grain varies with different species being greater in rice and its milled products than in hard wheat.

III. — Results of a study of wheat which had been frozen in the field before ripening (1) indicated that the grain thus frozen and subsequently thawed, respired more vigorously when stored in bulk than normal wheat of the same moisture content.

It was considered likely that the increased portion of substrate may have accelerated the reaction induced by the enzymes, and thus resulted in the respiration of more carbon dioxide per unit of time, and consequently the liberation of more heat energy.

Tests were carried out by freezing and then thawing the entire plant before ripening to discover if there was a difference in the respiration of such material and of plants not frozen.

---

(1) See *R* June 1919, No 707. (*Ed*).

From the data secured it appeared that the frozen plants respired more vigorously during the first 24 hours after thawing than the others These suggest that the extent of damage to the grain, viewed from the milling and baking standpoint, may be indicated by the relative difference in respiration between plants frozen and thawed and others harvested at the same time but not frozen. But when a point is reached in the maturing where freezing and thawing do not accelerate respiration, it seems decidedly improbable that the grain will be affected in its milling qualities by such treatment. That moisture content is important is indicated by the data. Dessication accompanying maturity suppresses the activity of the enzymes responsible for respiration and doubtless similarly suppresses the hydrolytic enzymes which unfavourably affect the quality of the grain.

IV. — The following table shows the respiration of normal and rust-infected Marquis wheat plants harvested on August 9, 1917.

Sample	Moisture in plant	Weight per 1000 kernels of dried grain	CO$_2$ respired in 24 hours	
			Per 100 gm of dry matter	Per plant
	per cent	gm	mg	mg
Normal plants	56.08	19.54	2.904	61.46
Rust-infected plants . .	46.41	20.44	1.608	39.16

If respiration of these tissues is in any sense a measure of metabolic processes, metabolism was decidedly depressed in the rust-infected plants. It is considered that this may afford an index to the metabolism of such infected material, and the consequent effect upon the filling of the kernel.

25 - **On the Gaseous Exchanges between the Root and the Atmosphere.** — CERIGHELLI R. in the *Comptes rendus de l'Academie des Sciences*, Vol. CLXXI, No 13, pp 575-578 Paris, September 27, 1920.

It was demonstrated a long time ago that the root absorbs oxygen and gives off carbon dioxide. What still remains to be discovered is the proportion in which these gases are respeetively absorbed and exhaled by the subterranean organ, and whether, under certain conditions, the root is not also able to absorb carbon dioxide, and finally, what factors take part in the successive processes.

The author undertook a series of experiments on roots in relation to the aerial parts of the plant, and on roots that had been detached from them. The plants used in the experiments were *Senecio vulgaris*, *Lupinus albus*, and *Laurus nobilis*; the method employed was the confined-air method, and the analyses were carried out with BONNIER and MANGINS apparatus.

From the results observed, the author drew the following conclusions :—

1) When in a confined space roots respire like all other plant organs, oxygen being absorbed and carbon dioxide given off in such pro

portions that the ratio $CO_2 : O$ varies from 0.7 to 1, according to the species.

(2) When the roots are in contact with a very moist atmosphere, respiration increases; the amount of oxygen absorbed is greater than in a dry atmosphere, as is also the carbon dioxide given out, and the ratio $CO_2 : O$ remains constant (in the case of roots sectioned in pumice-stone).

(3) When the roots are in contact with a very moist atmosphere and connected with the aerial parts of the plant, respiration still increases, but all the carbon dioxide formed during the process is not completely exhaled, some of it being carried into the upper portions of the plant. in which case the respiratory ratio is very low. This phenomenon appears to be connected with the absorption of water by the root, for it seems that it is the absorbed water that carries with it the carbon dioxide

The author has never observed any absorption of carbon dioxide, at least in a gaseous condition. On the other hand, he thinks that the carbon dioxide originating in the root may play a more important part than that dissolved in the soil water, and absorbed at the same time as the latter.

26 - The Nitrogenous Matter and Phosphoric Acid Present During the Maturation and Germination of Wheat.

— ROUSSEAUX, E and SIROT, in the *Comptes rendus de l'Académie des Sciences*, Vol CLXXI, pp 578 580 Paris, September 27, 1920

In their previous work on the baking qualities of flour the authors have shown that in the flours made from normal, completely ripe and properly harvested wheat, the ratio of the soluble nitrogen to the total nitrogen present is almost constant in good baking flours. In flours that take badly, the proportion of soluble nitrogen varies from this constant (1).

Subsequently, they estimated the variations in the nitrogen, phosphoric acid and acid contents, not only of the flours but also of by the wheat itself. Analyses were made of average samples of wheat gathered every 5 days in the same field from the setting of the grain until the harvest; and then seeds from the beginning of germination until the emergence of the seedling. The results may be summarised as follows: —

The total nitrogen varies little; it increases and then decreases slowly and slightly as the carbohydrates increase. If, however, the percentage of the total nitrogen varies but little, the conditions under which it exists differ greatly. At first, 40 % of the nitrogen is soluble, but its solubility gradually decreases till only 9 % is soluble At this point, a fresh slight increase of solubility manifests itself, and 3 or 4 days later, an almost stable condition of equilibrium is reached, the proportion of soluble nitrogen being about 14 %. This stable condition appears to coincide with the chemical maturation that appears to precede the harvest by a fortnight. The ratio of soluble nitrogen to total nitrogen remains about 14 %, as long as the condition of the wheat is normal, but should it begin to germinate, the amount of soluble nitrogen rapidly increases rising to 26 % in the distended, germinating seed, and to 52 % in the embryo itself.

---

(1) See *R.*, May, 1913, No. 605; *R.*, Mar., 1918, No. 343. (*Ed.*)

The behaviour of the phosphoric acid is in every way similar to that of the nitrogen ; the percentage is at first almost uniform, but falls from 76 to 30 % to rise slowly to, and remain at about 35 % In the germinating seed, it increases rapidly to 42 %.

The parallelism in the variations of the nitrogen and phosphoric acid is not without practical interest. It is possible to admit a correlation between a scarcity of available nitrogen in soils, and the low gluten content of wheats with a heavy yield, but it appears that this could not be remedied by the increased application of easily-nitrifiable nitrogenous fertilisers, unless a large supply of phosphatic manures were given at the same time.

During maturation, the acidity distinctly and regularly falls, declining from 0.300 to 0.016 to rise again to 0.048 in the germinated grain.

To sum up, wheat reaches normal and complete maturity when a state of equilibrium is reached, which as far as the nitrogenous and phosphatic matters are concerned, consists in the existence of a certain ratio between the soluble and insoluble materials. Any other ratios denote insufficient maturation, or a tendency to germination, which means that the condition of the wheat, or the flour, is more or less unsuitable for bread-making.

27 - **Development of Barley Kernels.** — I. HARLAN, H. V. (Agronomist in Charge of Barley Investigations, Bureau of Plant Industry), Daily Development of Hannchen Barley from Flowering to Maturity in *Journal of Agricultural Research*, Vol. XIX, No. 9, pp 393-429, figs. 17, pl. 9. Washington, Aug. 2, 1920. — II. HARLAN, H. V. and ANTHONY, S. (former Technologist in Bailey Investigations), Development of Barley Kernels in Normal and Clipped Spikes and the Limitations of Awnless and Hooded Varieties. *Ibid.* pp. 431-472, figs. 13, pl. 6.

I. — This paper presents data showing the growth of the Hannchen variety at Idaho from flowering to maturity taken at 12 hour intervals. This period in three successive years was 26 days The experiment differs in method from that employed by former investigators in the fact that there is a reduction of the period between the samples taken, and also an extensive study is made of the physical indices of length and diameter of the kernel.

In the early stages of development, measurable growth was observed daily and during 24 hour intervals. The length growth was completed by the seventh day, and as soon as the rate of growth in length decreased, the lateral diameter showed its most rapid increase. The dorsoventral diameter continued to increase almost until maturity.

Attention is drawn towards: 1) The effect of the position of the kernel on growth. Two main factors affected the relative size, *viz.*, age and the placing of the kernel on the spike. Graphs illustrate the comparative rate of development according to this position. 2) The course by days of dry matter, water, nitrogen and ash. The increase in dry matter was very uniform throughout the period of growth, and the water percentage decreased uniformly. The carbohydrates increased most rapidly and ash least rapidly. 3) The periods of development. This while steadily progressve from flowering to maturity, varied considerably in its nature. About the fifth or sixth day after flowering, the growth in length was checked and a rapid gain in dry matter began. About the ninth or tenth day a sticky substance caused the glumes to adhere to the kernel. About the fifteenth or sixteenth day, the kernel toughened, and the lemma began to lose colour in the centre of the dorsal surface. The awns which with this variety are more or less deciduous, dropt off in large numbers. This date coincided with the maximum water content of the kernel, and the end of the period of most rapid increase in dry matter and ash, and the completion of a stage of starch infiltration. From then onwards until maturity, the changes were gradual and differed only in degree. The only point which might mark a change of nutrition was found in those varieties which develop anthocyanin colours in the external layers a few days before maturity, but at present this is not known to be associated with any vital phase of growth or maturation.

A microscopical examination was made to determine the progress of the internal modifications that must accompany development. Plates illustrate starch infiltration at various stages. The first starch was found in the older cells in the middle of the flanks. The new cells added near the furrow developed in a way entirely comparable to the first cells of the starch endosperm. The actual date when growth ceases even where the external conditions are unusually uniform, must depend on the temperature and humidity at the time of ripening.

II. — There is a strong prejudice amongst farmers in the United States against the growing of barley because the long rough awns make the crop disagreeable to handle, the beards, in the straw and hay often cause sore mouths in stock, and the awns work into the wool of sheep.

The authors have proved the mistake made by clipping the awns in experiments carried out with the Manchuria barley in Minnesota and the Hannchen barley in Idaho. Both the material and the conditions were more favorable for satisfactory investigations in the latter district compared with the former.

In both cases the barleys did not yield as well as the bearded sorts and were readily shattered. It was evident and in accordance with former investigations, that the reduction in yield was not due to any injury to the plant, as the difference in growth was not apparent for several days after the awns had been removed and the kernels in both clipped and normal spikes were equally vigorous. It was only when starch infiltration became rapid that the awned spikes showed greater activity and resulted in a smaller volume and lower weight of dry matter at maturity with the kernels from clipped spikes than those from normal spike. There was only a slight difference in the quantity of nitrogen The water per kernel was a good index of development. Normally, the water rapidly increased after fertilisation and quickly attained the maximum. It then remained stabilised, or nearly so, as long as growth was efficiently maintained. When this was checked and maturation began, the water content dropt slowly until complete ripeness occurred. At this stage it dropt still more rapidly for two or three days. This was notably accelerated in the case of the clipped spikes. The average percentage of water in the normal spike was 34.19 on August 2nd

(Hannchen barley) dropping to 28.09 in August 3rd as compared with 32.1 dropping to 22.4 in the clipped spike.

The graph showing the percentage of ash in the kernels, rachises, paleae and awns of normal and clipped spike in this same barley showed that the awn contains a surprising amount of ash. At the flowering time, 10 % dry weight is ash, and at maturity 33 %. When the awns were removed this ash was apparently deposited in the rachis. It was in the rachis that the greatest and most significant difference occurred; the clipped spikes contained 25 % more ash than the normal spikes. This probably accounted for the tendency to shatter. Hooded and awnless barleys were found especially liable in this respect, and there seemed to be physiological reasons which accounts for this effect, namely: — the disposal of the ash as noted above, and also the removal with the awn of tissues and organs containing cells which can be used for storage purposes and which must necessarily cause some derangement of the normal processes of development.

The authors suggest the possibility of producing non shattering hooded and awnless sorts by using parents which normally have a low percentage of ash in the rachises. Several hundred hybrids with smooth awns have been produced and tested and several give promise of good yielding capacity. Whether varieties of this type can be made to yield equally as well as the awned sorts, remains yet to be determined.

28 – **The Molecular Concentration of the Sap of Vines.** — CAUDA, A and MENSIO, C. in *Le Stazioni sperimentali agrarie italiane*, Vol. LII, Parts 7, 8, 9, pp 317-331 Modena, 1920.

A knowledge of the molecular concentration of the saps circulating in plant tissues is of paramount importance in judging of the richness of the soil, measuring the rate of absorption of fertilising salts, tracing the accumulation of mineral substances in the plant, estimating the amount of salts circulating in the tissues during the different phases of the plant's development, and, in fact, in solving many of the problems of plant physiology.

The molecular concentration of the sap can be determined either by estimating the amount of ash, or by ascertaining the electric conductivity of the said sap, or by means of other physico-chemical methods. The authors adopted the method of determining the electric conductivity, and selected the vine as the subject of their experiments, using the liquid exuded from the " bleeding " stem of the vine, and sap expressed from the vine shoots. From the results set forth in a series of Tables, the authors drew the following conclusions: —

The liquid flowing naturally from the stems of pruned (bleeding) vines is rich in mineral and organic matters; and has an average concentration of 69×10^{-5}; this is a sign of the vigour and earliness of the plant. The determination of the electric conductivity seems to be the most adapted to the end in view, for it is influenced, not only by the amount of mineral substances present in solution, but also by the presence of organic matters, especially those with an acid reaction.

In vine sap, there is no absolute ratio between ash and extract though, as a rule, the ash amounts to from $^1/_5$ to ½ of the total extract.

The electric conductivity increases with the increase in mineral matter (ash) contained in the exuding sap of the " bleeding " vine. Therefore, given a constant quantity of mineral substances, the higher the percentage of extract, the higher is the electric conductivity.

There is a direct ratio between the acidity of this vine sap and the percentage of extract. The electric conductivity increases with the acid content, and attains a maximum after which it declines.

The concentration of the sap of the " bleeding " vine varies between vines of the same locality, between grafted vines and those growing on their own roots, and also according to the system of cultivation and the vigour and age of the plant. In young, robust vines, the electric conductivity is high; vines grafted on American stocks have more concentrated sap than those of the same variety growing on their own roots.

It is probable that the high electric conductivity of the sap of the " bleeding " vine is a sign of a heavy crop of grapes.

29 - **Studies on Self-sterility** (1). — EAST, E M (Harvard University), in *Genetics*, Vol. 4, No. 4, pp. 341-363, bibliography of 7 titles. Princeton, New Jersey, July, 1919.

In 1917, EAST and PARK described the belaviour of self-sterile plants in some detail, and a series of 3 papers in connection with this subject has now been issued dealing with: (1) The relation between self-fertile and self-sterile plants; (2) selective fertilization; (3) the behaviour of a number of families of self-sterile plants under various schemes of mating.

I. RELATION BETWEEN SELF-FERTILE AND SELF-STERILE PLANTS (" Studies on Self-sterility. " *Genetics*, 2, pp. 505-609. EAST and PARK). — Experiments made by COMPTON (1912-13) with *Reseda odorata* showed that: (1) Self-sterile plants intercrossed produced only self-sterile offspring. (2) Certain self-fertile plants then self-fertilised threw approximately 3 self-fertile to 1 self-sterile offspring. (3) These same plants when crossed with self-sterile individuals, produced self-fertiles and self-steriles, ratio 1 : 1. (4) Other self-fertile plants yielded none but self-fertile offspring from selfed seed.

These experiments were corroborated by the author by crossing *Nicotiana Forgetiana*, and *N. alata* with a third species. N. *Langsdorffii*, which is consistently self-fertile.

Data are reported showing that in *Nicotiana*, self-sterility is due to the presence of the allelomorph of a dominant fertility factor *F*. When a population is homozygous for this factor *ff*, it is self-sterile.

The factors which control the peculiar and systematic behaviour of self sterile plants when intercrossed among themselves are wholly independant of this factor, and the latter need not be considered in an interpretation of their expression.

---

(1) See *R.* Nov.-Dec. 1920, No. 1077. (*Ed.*)

The manifestation of self-sterility as evinced by the degree to which pseudo-fertility shows, is due to as subsidiary inherited factor (or factors) but without the presence of the principal factor *ff*, there is no evidence that it functions.

II. SELECTIVE FERTILISATION (1). — The conception of the "gene" is unquestionably the foundation of genetics. The author considers that possibly the genes are arranged spatially, and a more delicate system of action is possible than with mere chromosome breaks. *The genes pass to either daughter cell by chance* and the gametes thus formed *mate by chance*. Experiments were made with the self sterile species. *Nicotiana Forgetiana*, *N. alata* and *N. augustifolia* to test the possibility of selective fertilisation. Comparisons were made between pollen tube frequency distributions of highly heterozygous and of comparatively homozygous plants, and also the influence of compatible matings on incompatible matings. In neither case was there any indication of selective fertilisation. Gametes are formed in may animals and plants, particularly in species crosses, which can never function.

The colour of *Nicotiana* pollen, the author states to be inherited as a maternal character; this corroborates BATESON'S experiments with sweet peas, in 1909. In BELLINGS work on the velvet bean (1914), 50 % of the F_1 pollen was found abortive in a certain cross. These facts point to the conclusion that unless mixtures of pollen from different individuals (or even spermatozoa) is used, selective fertilisation is quite improbable.

III. FAMILY OF SELF-STERILE PLANTS WHOLLY CROSS-STERILE. — The author has found it possible to obtain seed from truly self-sterile plants, and from combinations that are fundamentally incompatible and has kept records of infertile and fertile crosses made on 54 plants of one family, and a comparison between the number of seeds in the capsules of the presumably pseudo-fertile combinations in this family and the number of seeds in the capsules of the same plants when pollinated with pollen from the plant of F_2 generation (*N. Forgetiana* × *N. Langsdorffi*) ; and also records of pollinations made on 25 plants of this same family with a single sterile plant of F_2 generation of the above mentioned cross. The behaviour of a number of families of self-sterile plants under various schemes of mating was described in a preceding paper (*Genetics*, Vol. I, pp. 311-333) and this combined with the present work in progress leads the author to state that continued self-fertilisation is possible by persistent efforts of self pollination carried to the very end of the flowering season, and should bring about homozygosis in the secondary factors affecting the behaviour of self-sterile plants among themselves. When such a point is reached, the resulting population should not only be self-sterile but should belong to a single class all members of which are cross sterile with each other.

30 – **Genetics of Rust Resistance in Crosses of Varieties of *Triticum vulgare* with varieties of *T. durum* and *T. dicoccum* from the Mendelian Standpoint.** — HAYES, H. K., in *Journal of Agricultural Research*, Vol. XIX, No. 11, pp. 523-542, pl. 6, bibliography of 27 works. Washington, Sept. 1920.

The artificially induced epidemic was produced with a known racial strain of the biological form *Puccinia graminis* f. sp. *tritici;* after first removing all *Berberis* bushes from the immediate vicinity of the rust plot in order to avoid infection by means of other biological forms of rust.

TABLE I. — *Rust infection of certain parent varieties and F_1 crosses between resistant and susceptible wheats.*

Variety or cross	Percentage of stem rust	Cross	Percentage of stem rust
Marquis	40 to 70 %	Marquis × Acme (C I 5284)	70 %
Preston	70	Preston × Acme (C I 5284)	70
Pioneer	40	Acme × Marquis	70
Acme	10	D–4 × Pioneer	40
D–4	10	Acme × Preston	70
Kubanka (C I 2094)	20	Marquis × *T. dicoccum*	10
Jumillo (C I 1736)	15	*T. dicoccum* × Marquis	10
T. dicoccum (Minn. 1165)	0	*T. dicoccum* × Preston	15
Marquis × Jumillo (C I 1736)	40	Preston × *T. dicoccum*	15
Marquis × Kubanka (C I 2094)	40 to 70		

Four durum varieties were then tested (Acme. D-4. Jumillo and Kubanka). The highest percentage of rust infection was 20 on Kubanka, while there was only 10 % on D.-4 and Acme.

Marquis, Preston and Pioneer were very susceptible to rust.

The behaviour of the F_1 cross was extremely interesting; whilst with an F_1, cross between *T. vulgare* vars., and durum wheats, susceptibility is a dominant character, a recessive character in crosses between *T. dicoccum* and common wheats was obvious.

For the purpose of determining possible interrelation between inheritance of rust resistance and other differential characters, the author undertook to determine the genotypic nature of individual F_2 and F_3 plants.

In the F_2 generation, numerous forms of *T. dicoccum, durum* and *vulgare* were evident, with various intermediary grades: Table II shows the predominance of the botanical characteristics of *T. vulgare* accompanied by a gradual susceptibility to rust.

Likewise in the cross *T. vulgare* × *T. dicoccum*, the author discovered an indication of linkage of durum or emmer's characters and rust resistance. It is, however, only a partial linkage, and if work is carried on with a large number of individuals, it will be found possible to isolate in F_3, plants possessing the characters of *T. vulgare* and the resistance of *T. durum*. In F_2 generation Marquis × durum, out of a total of 128

common segregates, only 2 were rust resistant, but both of these were of little commercial value. However, several resistant plants with the head characters of common wheats were obtained in the F_2 generation. With the crosses Marquis × *dicoccum* 1165, and *dicoccum* (C I 1524) × Marquis, out of a total of 73 plants, only one was obtained in the F_2 generation which resembled *T. vulgare* and this was susceptible to rust. Several plants were obtained in the F_3 generation which were not only rust resistant, but also resembled *T. vulgare.* These facts show therefore, that it is possible to transfer the rust resistance of emmer wheats to common wheats by crossing and subsequent selection. There is, however a partial linkage between rust resistance and the emmer head type which makes it essential to grow large numbers in the F_2 and F_3 generations.

The mode of inheritance of rust resistance seems entirely comparable with the general mendelian manner of inheritance of botanical and morphological characters. The technique of breeding for rust resistance is similar to that of breeding for agronomic characters.

31 - **New Varieties of Wheat Obtained by Hybridisation in Australia.** —See No. 42 of this *Review.*

32 - **Development of Awnless and Hooded Varieties of Barley in the United States.** — See No 27 of this *Review.*

33 - **Occurrence of the Fixed Intermediate, Hordeum intermedium Haxtoni, in Crosses between *H. vulgare pallidum* and *H. distichon palmella*** — HARLAN, H V. and HAYES, H. K , in *Journal of Agricultural Research*, Vol. XIX, No. 11, p. 575-591, pl 4, bibliography of 9 works. Washington, D. C , Sept. 1920.

The cultivated barleys belong to the genus *Hordeum* and are characterised by the presence of 3 single-flowered spikelets at each node of the rachis.

The 6-rowed parents in all the hybrids studied, belonged to the variety *H. vulgare pallidum* and include Manchuria S. P. I. No. 20375, Sexradigt, Odessa, Reid Triumph, Surprise and a hybrid 6-rowed × 2-rowed barley. The lateral as well as the central florets of these varieties are long-awned and produce well-developed kernels. The 2-rowed parents all belonged to the variety *H. distichon palmella.* The central florets are long-awned while the lateral ones are awnless with rounded tips, and are sterile. Of the varieties here mentioned, Svanhals, Garton and Primus belong to this group.

In *H. intermedium Haxtoni,* the central florets are long-awned and produce normal kernels, while the lateral florets are awnless, as in the 2-rowed barleys, but fertile, producing undersized kernels. This form, obviously intermediate in character between the 6-rowed and 2-rowed barleys, has proved to be constant and fixed.

The cross Manchuria × Svanhals produced progeny amongst which the fixed intermediate occurred in the ratio 1 : 16 (approximately). The stability of this form was established by observations on intermediates obtained from several crosses. Some of these homozygous intermediates have been grown since 1912 with no indication of reverting to either the

6-rowed or the 2-rowed parental type. No 2-rowed segregates appeared among the progeny of the 6-rowed × *intermedium* crosses, and no 6-rowed segregates appeared among the pregeny of the *intermedium* × 2-rowed crosses. Every hybrid so far studied indicates that *H. intermedium* has a genetic rank equal to *H. vulgare* or *H. distichon.*

According to the results obtained with a large number of F_2 and F_3 progeny, a 2-factor hypothesis for fertility in the lateral florets is suggested. On the " presence-and-absence " hypothesis, the 6-rowed barleys are supposed to be homozygous for the presence of the epistatic factor A, the *intermedium* to be homozygous for the presence of the hypostatic factor B and for absence of the epistatic factor (*a a BB*), and the Svanhals to be homozygous for the absence of both factors (*a a b b*).

According to the hypothesis, there are 2 types of 6-rowed barleys. The Manchuria parent is supposed to be homozygous for the 2 factors (A A B B), while certain regressive 6-rowed segregates are thought to be homozygous for the presence of A and the absence of B. (A A bb).

F_2 is therefore constituted as follows : 1 AABB ; 2 AABb ; 1AAbb : 2 AaBB ; 4 AaBb ; 2 Aabb ; 1 aaBB ; 2 aaBb ; 1 aabb)

From the data collected in connection with the cross Manchuria × Svanhals, there is evidence suggestive of the existence of a third factor C. which affects the vigour of the lateral florets and their percentage of fertility.

34 – **The Inequality of Reciprocal Maize Crosses.** — RICHEY, F. D., in the *Journal of the American Society of Agronomy*, Vol. 12 Nos. 6-7, pp 185-196, 1 fig., bibliogr. of 15 works. Washington, D. C., September-October, 1920.

The author compares the yields of three pairs of recipricocal crosses between commercial varieties of maize and shows inequality in each pair. Data also are given which show that in one pair of these reciprocals the inequality is caused by the inheritance of some character from one of the parent varieties only when that variety is used as the staminate parent. The crosses were made by growing rows of the varieties used as pistillate parents between rows of those used as staminate parents and detasselling the former rows before they had shed pollen. In every case the maize was planted thick and later thinned to the desired stand. All yields were corrected to a basis of air-dry shelled maize.

Conclusion. — The author suggests that some type of sex-linked inheritance must at least be considered as a possible cause of inequality between the crosses as shown by the unequal transmission from the Selection " Fraley Yellow Dent " as staminate and as pistillate parent. A difference in the food materials furnished the young plants by the different maternal parents and in germinal reactions with different cytoplasms has been suggested as also a possible cause of inequalities.

35 – **On the Hybrid Euchlaena : Maize for Forage Purposes.** — COLLINS, G. N. and KEMPTON, J. H., in *Journal of Agricultural Research*, Vol. XIX, No. 1, pp. 1-37, pl. 7. Washington, D. C., April 9120.

The genetic relations of the principal characters of maize and teosinte (*Euchlaena mexicana* Schrad.) were investigated in a cross between the Tom

Thumb pop-corn and Florida teosinte, a large forage grass genetically distinct from maize. One of the objects of the experiment was to determine to what extent the characteristics of the parents would be dissociated in the hybrids, and to what degree of freedom, recombined. Would the much-branched habit of teosinte continue to be associated indefinitely with a teosinte-like inflorescence, or would profusely branched plants appear bearing maize-like ears ? Would the early maturing plants all resemble maize or would there be early plants having the desirable forage characteristics of *Euchlaena ?*

FIRST GENERATION (F_1). — The 4 normal F_1 plants were examined when about 18 dcm. high with 6 or 7 suckers arising from nodes below the ground. These suckers usually equalled the main stalks in height, but flowered several days later (similar to maize). The branching of the main stalk was not continuous ; one or two nodes usually failed to develop branches. The total number of nodes on the main culm ranged from 17 to 21.

The terminal panicles ressembled those of the maize in that they all had 8-rowed central spikes instead of 4 as in teosinte ; however, in 3 of the 4 plants this spike drooped as in teosinte.

The F_1 plants were comparatively uniform, and showed characters which, for the most part, were intermediate.

SECOND GENERATION (F_2). — The F_2 plants were also intermediate, with a greatly extended range of variation. Thirty-three of the characters that differentiate the parents were selected for examination. The distribution of the characters with one or two exceptions showed little or no evidence of alternative or Mendelian inheritance. With respect to the individual characters, the extreme variants approached, and in same cases exceeded those of the parents. Results in general showed the greatest freedom of recombination ; it is true that there were many instances of coherence or partial coupling of characters, but there were an almost equal number of instances where characters derived from different parents showed a tendency to combine more frequently than would be expected as the results of chance.

While there appeared to be no incompatible combinations, there were on the other hand no completely independant characters. Every character recorded showed significant correlation with other characters, and these in turn were correlated with still others with the results that all the characters were interrelated and formed a single group in which there is no coefficient of correlation lower than ± 0.31.

MENDELIAN INHERITANCE. — The nearest approach to Mendelian inheritance was shown by the arrangement of the spikelets in the pistillate inflorescence. In maize, the female spikelets are borne in pairs ; in *Euchlaena* on the other hand, thay are borne singly. Dominance of the male character was complete in the F_1 generation. In F_2 the segregation was not complete, there being many plants with both single and double female alicoles ; but the number of individuals in which double female alicoles predominated was approximately 3 times the number in which there were more single female alicoles.

It was found that the characters of the pistillate inflorescence were subdivided in transmission to a remarkable degree: Thus the maize ear, instead of behaving as a unit, was subdivided into a large number of separately inherited units all of which were inherited more or less independently.

PRACTICAL POSSIBILITIES. — A suprisingly large number of the plants combined the abundant production of suckers characteristic of the *Euchlaena* parent with the sturdy, upright character of maize, and resulted in very leafy compact plants of a type that should prove valuable for forage purposes.

It remains to be seen whether the new combinations can be maintained and made to breed true. The results of previous experiments with maize hybrids would indicate that selection for a few generations will fix any desired combination.

36 - **Contribution to the Technique of the Selection of *Brassica* Varieties.** — BECKER J., in *Zeitschrift für Pflanzenzüchtung*, Vol. VII, Part. 2, pp. 91-[illegible], Berlin December, 1919.

During the war, many apiculturists having no special knowledge of the subjects turned their attention, with the sole aim of making money, to the production and sale of the seed of selected varieties of *Brassica* (as they termed them), thus destroying, to a certain degree, the results of the patient and conscientious labours of specialists, who had gained for Germany world-wide reputation in this branch of selection work.

It is most necessary to repair the damage done. The article analysed gives the outlines of a method for the selection and improvement of the following varieties of *Brassica: B. oleracea capitata, B. oleracea sabauda, B. oleracea gemmifera, B. oleracea gongyloides, B. oleracea botrytis, B. oleracea acephala.*

From a field of homogeneous material, 3 or 4 plants with the desired characters are chosen and kept through the winter.

In the spring, these 3 or 4, individuals are planted together, and isolated, so as to form what is called the " reproduction lot ". The number of such plants should not exceed 4, otherwise the number of combinations in the progeny would increase to such a point as to make the further work of selection, and the fixation of types, both very difficult and less satisfactory.

The plants are lifted before they are ripe, and placed in a sheltered and covered place, where they can mature properly. The seeds from the *fifty* best stems are collected separately in small bags, whereas the rest are put into a single bag, and constitute the " second seed ". The separation of the seed from each stem is necessary, on account of the frequent variation in shoots that are thus isolated, and which must be taken into account, especially in the case of *Brassica*, where these variations are of somewhat common occurrence. Towards the end of spring, or at the beginning of summer, the seed of each stem is first put to germinate in filter paper, or Petrie dishes; as soon as the seeds have germinated, they are transferred with forceps to small pots 5 cm. in diameter (one plant being put in each pot), and the latter are sunk on in beds of manure 12 m., long and 1.5 m., wide; 7200 plants are placed in each bed.

As usually 20 seeds are taken from each inflorescence, and 25 out of the 50 stems chosen are set apart, 500 pots are necessary for each reproduction lot. Each bed can therefore contain the progeny of about 14 of the latter.

It is advisable to use pots, for these not only insure absolutely uniform conditions of environment to the seedlings, but also enable the latter to be planted out without any risk of injury.

When the crop is lifted (Sept.-Oct.), the 10 best plants from each family are taken, and put for the winter in a dry well-ventilated cellar; the rest being piled up in the fields and covered with a little soil (second lot).

In the spring, 4 out of the 10 chosen plants are isolated in a group, and allowed to intercross freely (the other 6 are kept in reserve). They are used for the continued production of *élite* seed. The plants of the second lot, which are to be used for breeding, are placed in rows, sufficient space being left between the latter to admit of free passage, and the carrying out of the necessay cultural operations. Naturally, in choosing and laying out the field, precautions must be taken to prevent cross-pollination, and the consequent production of hybrids.

The crop is lifted as soon as the inflorescences begin to wither: the yield varies within very large limits, it may be from 50 to 500 kg., per hectare; the seed collected is sufficient to sow from 100 to 1000 hectares.

Brassica seed can be obtained in 3 ways.

1) From *female parent plants* lifted in the autumn, stored during the winter, and planted out in the spring;

2) From *stumps* transplanted in spring, the cabbage-heads having been cut in the autumn; the stumps are left in the ground during the winter, and transplanted in spring for seed production;

3) From *cuttings;* these are planted in the autumn, they winter in the open field, and bear seed the following year. The author has carried out some experiments with a view to determining which of these methods is the best for obtaining a good seed yield. The following Table summarises the results of his work.

	Date of ripening of seeds	Average number seeds per plant	Average number of unfertilised flowers per plant	Average number of shoots (barren) per plant
Female parent plants. . . .	28 VII	1471	592	887
Stumps	7 VIII	857	573	284
Cuttings.	9 VII	630	227	453

The best results were therefore obtained with entire, well-developed mother plants, which had been kept through the winter, and planted out the following spring.

37 - **Crosses between Varieties of Brassica.** — RAGIONIERI, A., in *The Gardeners' Chronicle*, Vol. LXVII. No. 1753, pp. 60, London, July, 31, 1920. — *Giornale di Agricoltura della Domenica*, Vol XXX, No. 42, pp.334-335. Piacenza, October 17, 1920

The improved Chinese cabbage (*Brassica chinensis* var *Pet-sai*), which was placed on the market some years ago by Messrs VILMORIN-ANDRIEUX and Co., Paris, possesses qualities that attract the attention of those engaged in hybridisation. The chief points about this plant are its rapid growth, the large number and succulence of the leaves growing in the centre and forming an elongated ball, like a huge Roman lettuce, and its savoury taste. Some years ago, the author made the following crosses at Castello (Italy).

(1) *Brassica oleracea* (forage cabbage, one of the white and purple varieties ♀ × *B. chinensis var Pet-sai* ♂.

(2) *B. chinensis Pet-sai* ♀ × *B. oleracea* (forage cabbage, one of the white and blue varieties) ♂.

(3) *B. chinensis Pet-sai* ♀ × *B. oleracea botrytis cauliflora* (cauliflower) ♂.

(4) *B. oleracea botrytis cauliflora* (cauliflower) ♀ × *B. chinensis Pet-sai* ♂.

(5) *B. chinensis Pet-sai* ♀ × *B. oleracea capitata* (white-headed cabbage) ♂.

(6) *B. chinensis Pet-sai* ♀ × *B. oleracea acephala viridis* (green Scotch kale) ♂.

(7) *B. chinensis Pet-sai* ♀ × *B. Rapa* (common turnip) ♂.

(8) *B. Rapa* ♀ × *B. chinensis Pet-sai* ♂.

Ten flowers were cross-fertilised. Crosses Nos. 1 and 2, made in the hope of obtaining good, quickly-growing forage varieties, were of no practical use. The seeds of No. 1 were imperfect, No. 2 produced 4 seeds that germinated regularly and gave 4 stalkless, strong plants with leaves intermediate in character between those of both parents, but resembling in shape the leaves of the female parent " Pet-sai ". The colour of the entire plant was a greenish-white, turning to pure white in the centre. Although they were grown in a sheltered spot, all these hybrids died during the winter.

No. 3 gave a few more or less perfect seeds, 3 of which germinated and produced 3 seedlings resembling the female parent " Pet-sai " but with no traces of a head, either of flowers, or leaves. Two of these plants died during the winter, but the third was self-fertilised and bore some seeds, which though they appeared imperfect, produced fifty very vigorous, stalkless plants of which $^2/_3$ of the leaves were entire, like those of " Pet-sai ", and $^1/_3$ were lobed like cauliflowers leaves. None of these plants bore fertile seeds. Crosses Nos. 5 and 6 produced no fertile seed.

The most important results were obtained from crosses 7 and 8. The improved Chinese cabbage has great sexual affinity for the common white turnip. All the fertilised flowers produced perfect siliquas full of fine seeds that germinated quickly. All the hybrids of the first generation were very vigorous, and the offspring of these reciprocal crosses showed no sign of a large and rounded root. The hybrids resulting from cross No. 8 had rather broader fusiform roots than those obtained from cross No. 7. The leaves were very broad, lobed like those of the turnip, but erect like the leaves of " Pet-sai ", though they did not make a true head with strong veins over the whole surface. These plants, when selfed, produced an enormous amount of seed, and were perhaps even more fertile than their parents. The recessive character (presence of large round root, and entire leaves) reappeared in the second generation in the Mendelian ratio.

Some hundreds of the young F_2 plants showed great variation in shape, the roots in certain cases being round and fleshy and of different forms and dimensions whilst in others they were more or less elongated, like the root of the horse radish. Some of the globe-rooted plants had entire leaves like " Pet-sai ,, and others had lobed leaves like a turnip. The tendency to form a head was observed in some of the hydrids with turnip-like roots, and also in others with elongated roots. When boiled, the leaves of these plants are tender and have a good flavour. The young shoots, which grow in large numbers at the beginning of spring, can be served like asparagus.

These experiments show that whereas there exists a strong sexual affinity, between *B. chinensis* and *B. Rapa,* the pollen of the former species has but a very weak effect upon the stigmata of the varieties of *B. oleracea.*

38 – On the Behaviour of the Hybrids *Raphanus Raphanistrum* × *R. sativus.*

— TROUARD-RIOLLE, S. in the *Revue générale d. Botanique*, Vol. XXXII, No. 282, pp. 438-447, figs. 3. Paris, October, 1920.

From the cross *Raphanus Raphanistrum* × *R. sativus* (or from *R. sativus* × *R. Raphanistrum*), hybrids that were much more developed than their parents were obtained in the F_1.

M. SEGRET had also obtained a similar result in crossing the pink, white-tipped radish with a hybrid cabbage (a cross between Volga Russian and Curled Savoy). The cabbage-radish thus produced attained a gigantic size.

All the varieties of *R. Raphanistrum* used in the experiment had yellow flowers whereas, as is well-known, most varieties of this plant have nearly always white flowers, sometimes slightly tinged with pink or violet, corresponding to the red (or pink) and violet (or yellow and black) colouring of the roots.

Taken as a whole, the F_1 hybrids may be said to have had white flowers in the first year. But this rule was not absolute, and did not apply to all the flowers. Further, on a plant with white flowers, shoots with yellow flowers were sometimes met with at the same time, or white flowers with 1 or 2 yellow petals, etc.

At first sight, the siliquas of the hybrids appeared intermediate between those of the two parents, both as regards external morphology and anatomy. Closer observation, however, revealed many points of difference and various combinations.

The author studied the *Raphanus* hybrids chemically, both from the point of view of the anthocyanins present in the roots and flowers, and also from that of the carbohydrates occurring in the roots.

R. Raphanistrum has normally only a small amount of sugar in its roots, whereas the starch content is high, being 3 to 4 gm., in 100 gm., of fresh material. *R. sativus*, on the contrary, when cultivated at the same time and under similar conditions, contains sugar, but not much starch. Thus on analysis a pink radish yielded 1.60 gm., of sugar, and 0.60 gm., of starch per 100 gm., of fresh material; the white-tipped pink radish contained 1.30 gm., of sugar, and hardly distinguishable traces of starch. The cross between the pink radish and *R. Raphanistrum* contained 1.90 gm., of sugar and 0.60 gm., of starch (therefore, intermediate conditions exist).

39 - Studies on the Transmission of Characters in Certain Cucurbitaceae Hybrids. —

LOTTY, J. P. in *Genetica*. Vol. II, Part 1, pp. 1-21, 9 fig., 1 plate. The Hague, January, 1920

Cucurbita maxima and *C. Pepo* represent two very distinct Linnaean species which are not capable of reciprocal crossing, as has been proved by the negative results obtained in the author's experiments

Both species produce numerous forms or varieties that are clearly distinguished from one another by a series of fixed and hereditary characters. These forms, which correspond to the small, or elementary, species of JORDAN can, even if they are very dissimilar, be crossed together, giving rise, in the F_2 to complex phenomena that give evidence of the segregation of characters.

CROSSES BETWEEN FORMS OF C. MAXIMA. — For this experiment, two varieties viz., the Turban pumpkin, and " Hubbards' green pumpkin " (1) were used that had the same type of leaves and differed considerably in the shape of the ir fruit.

By crossing Turban Pumpkin ♀ with Hubbards' Green Pumpkin, ♂ 9 plants were obtained in the F_1, and of these only 2 produced fruit by self-fertilisation. These two plants were known as Nos. 12.1, and 12.5 respectively.

The fruits borne by these plants may be regarded as intermediate, both in shape and colour, though they more nearly resembled the fruits of the Turban Pumpkin, than those of " Hubbards Green Pumpkin ".

They are round and rather flat, but the character of " swelling at the extremity " is reduced to a more or less deep incision developed round the extremity; they are reddish, with some white and greenish spots with a single, circular, green zone corresponding to the extremity.

---

(1) As the excellent figures and the coloured plate cannot be reproduced here, a short description of the fruits of the two varieties will be useful: —

" Turban pumpkin ": fruit characterised by a swelling (sometimes spherical) situated at the extremity : it has from 4 to 5 sides and is light red with white and green marbling.

" Hubbard's green pumpkin ": fruit badly-shaped, spherical, slightly tapering at both ends, coloured dark green. *Ed.*)

From the seeds of one fruit of the F_1 (12.1 *b*), 45 plants of the F_2 were raised in 1917, and only 3 of these bore fruit. This generation is indicated by the number 7 (7.1, 7.2 ... 7.44, 7.45).

In this second generation, there were a large number of shapes and the most varied shades, which showed the results of the segregation of characters in the hybrids of the two varieties of the *Cucurbita maxima* studied. It is very difficult to determine the genetic factors that come into play, on account of the great fluctuation and variability of the characters, as is seen by the considerable differences existing between fruits borne by the same plant. In any case, however, as far as the red colour is concerned, it is easy to recognise the character of a monohybrid, for out of 45 plants, 33 were red according to the ratio 3 : 1. Red is thus dominant as regards green. None of the fruits were, however, entirely red, there was always some green about them, at least at the extremity. This green patch often extended and crossed the groove surrounding the cap-like top. Touches and patches of green are also met with in the " Turban Pumpkin " ; in the hybrid, these colours are apparently strengthened by the " green Hubbard pumpkin ". As regards the cap of the Turban pumpkin, this character has proved to be liable to great variation, for in the same plant some of the fruits have a well-developed swelling, whereas in others this character is hardly discernable.

Of the 45 plants of the F_2, however, 3 (7.18, 7.21 and 7.27) had completely smooth fruits with no trace of groove or cap This gives the ratio 15 : 1, from which it must be concluded that the groove or cap depends upon the presence of 2 factors or determinants.

The study of the F_3 generation, which the author intends to undertake, will give more information as regards the genetic character of the material. The existence of many determinants, and hence the possibility of very many combinations, can already be deduced by analogy with the combinations obtained with the large number of chromosomes (12), found by M. LUNDEGARDH in the aploide of *Cucurbita Pepo*. With 12 chromosomes, $2^{12} =$ 5096 different gametes are obtained, and $5096 \times 5096 =$ more than 25 million combinations.

From what has been said, it is naturally difficult to obtain new, stable kinds of pumpkin by crossing different varieties of *Cucurbita maxima*.

From the cross Turban pumpkin ♀ × Silver-grey pumpkin ♂ (1), an F_1 was obtained containing individuals of intermediate character with a well defined, though much smaller cap than the ♀ parent. In the F_2, contrary to what occurred in the F_1, the size of the turban instead of being the same, varied within considerable limits. From one plant of the F_2 with a very small cap, fruits with Turbans of all dimensions were obtained in the F_2, some of them being even larger than that of the female parent.

As regards colour, red prodominates over green and all the other colours In the F_2, there were hybrids with red, pink, flesh-coloured, pale yellow, dark yellow, white, dark-red, light-red, grey and other coloured fruits, whereas in the F_1 all the pumpkins were red.

---

(1) Flat wheel-shaped fruit of a dark dirty-green colour. (*Ed.*)

Grey predominated in its turn over brown and green. From the seeds of grey fruits obtained by the self-fertilisation of an F_2 plant, 37 plants with brown or green fruits (without trace of red) were obtained in the F_3. This second experiment (Turban pumpkin × Silver grey pumpkin) again proves that the different forms of *Cucurbita maxima* can be crossed, and that they give rise to Mendelian phenomena.

CROSSES BETWEEN DIFFERENT FORMS OF CUCURBITA PEPO. — Crosses were made between " Vegetable Marrow " and " Regenschirm " (Regenschirm = " Patisson " properly so-called = " Artichaut d'Espagne " = " Bonnet d'électeur " = " Arbouse d'Astracan, according to NAUDIN).

" Regenscherm " is a non-climbing plant of bushy habit and is a free-grower; its fruits are flat and yellowish white in colour; seen from above, they look like small open umbrellas (hence the name of the variety). " Vegetable Marrow " a climbing, free-growing plant with cylindrical, yellow fruits.

The hybrids of the F_1 were climbers like the male parent " Vegetable Marrow ", and had elongated, oviform fruits. As regards their colour, 2 of the plants bore dark-yellow fruits, 1 had yellow fruits with orange spots, and the three others had yellow fruits.

In all probability, the specimen of Regenschirm used in the cross was a heterozygote as regards the characters yellowish-white and orange, the first being dominant over the second. The colour of the hybrids of the F_1 with orange fruits, was the result of the combination of the " orange " gamete of Regenschirm with the " yellow " gamete of Vegetable Marrow, whereas the colour of the fruits borne by the other plants resulted from the combination of the " yellowish-white " gamete of Regenschirm and the " " yellow " gamete of Vegetable Marrow. This latter gamete, when present at the same time as the yellowish white gamete gives a more or less, intermediate shade.

The F_2 of an orange fruit of the F_1 was extraordinarily complicated, being of all possible colours, tints, and shades from yellowish-white to orange, and passing through the intermediate shades of bright yellow and dark yellow; from light green to dark green and blackish-green; in addition some fruits were coffee-coloured, a shade that had never been seen before. There was the same variety in the shape of the fruits which were spherical cylindrical, turbaned, apple-shaped, pyriform, etc.; the surface of the fruit might be smooth or wrinkled, of a uniform colour or variegated, spotted, mottled, etc.

Although these characters were subject to great fluctuations, yet we must admit the existence of a rather complicated structure, and of Mendelian phenomena that are far from simple.

By the selfing of an individual of the F_2 (8.12) having fruits of a light brown (*café au lait*) colour, 28 hybrids of similar colour, but of the most varied shaped, were obtained in the F_3. Therefore the plant 8.12 was a homozygote as regards colour, but a heterozygote as regards shape.

An individual of the F_2 (8.20), with pyriform, wrinkled fruits of a dark green colour, produced in the F_3 offspring that were heterogeneous from the point of form and rugosity, but homogeneous from that of colour, all the fruits being orange, either uniform or mixed with green. Here orange is dominant as regards green. As however, all the fruits before becoming orange passed through a green stage, it may be admitted that the female parent would also have assumed as orange tint in time.

From 8.31, a plant of the F_2, with pyriform, flattened fruits, hybrids were obtained with fruits of a uniform orange colour, but also heterogenous as to form.

Finally, from 8.32, a plant of the F_2 with apple-shaped fruits of a dark orange colour, were obtained, in the F_3, hybrids of very varied shapes, but nearly all with orange coloured fruits, there being only a few green or light-brown specimens.

On comparing the data obtained in the F_3 with those referring to the F_2, it appears that, as a rule, the first generation is les polymorphous than the second.

Although it was not possible to determine individually all the genetic factors or determinants implicated, it can, however, be stated with confidence that the different forms of *Cucurbita Pepo*, when crossed amongst themselves, give rise to Mendelian phenomena.

CROSS " ORANJE APPEL (ORANGE PUMPKIN) × VEGETABLE MARROW. — " Oranje-Appel ", according to NAUDIN, would seem to be a variety of *Cucurbita Pepo*, but other writers regard it as another species, *Cucurbita auriantiaca*. It has luxuriant climbing stems, and small fruits of the size of an orange and dark orange in colour.

In effecting reciprocal crosses (Oranje-Appel ♀ × Vegetable Marrow ♂, and Vegetable Marrow ♀ × Oranje-Appel ♂) between these two forms, very different results were obtained in both cases. With Oranje-Appel as the female parent, the fruits were smaller than when Vegetable Marrow was the female parent. This difference also occurs in the F_2; hybrids with Vegetable Marrow as a grandmother bear much larger fruits than those of which the grandmother is Oranje-Appel. There we have a case of transmission from the maternal side (matrocline hydrids).

GENERAL CONCLUSIONS. — (1) The Linnean species *Cucurbita maxima* and *Cucurbita Pepo* are composed of numerous varieties or constant forms (JOURDAIN'S elementary or small species).

(2) The elementary species belonging to the same Linnean species can easily be crossed, and produce fertile hybrids giving in the F_1 many cases of segregation of characters.

(3) Crossing experiments between forms belonging to different species have hitherto given negative results.

(4) Given the large number of experiments, made with negative results, it may fairly be assumed that neither *Cucurbita Pepo*, nor *C. maxima*, can be crossed with *C. melanosperma*; it can also be stated that it is not possible to cross *C. Pepo* with *C. maxima*, although the experiments in this case have been fewer.

(5) Hybrids obtained by crossing *C. Pepo* and *C. aurantiaca* Willd. are fertile and give rise to segregation phenomena, just as if the parents had belonged to two varieties (JOURDANS' species) belonging to the same species. It should however be noted that NAUDIN regards *C. aurantiaca* as a very definite variety of *C Pepo*.

(6) Reciprocal crosses between *C. Pepo* and *C. aurantiaca* show certain differences in the length and other dimensions of their fruits, differences, in every case, of a matroclinal character. Although very improbable, it is not absolutely impossible that this occurrence may be due to the heterozygous nature of the forms crossed, seeing that the characters in question are always transmitted on the maternal side.

(7) In no case was parthenogenesis or apogamy observed.

(8) Some of the forms studied were parthenocarpic.

40 - **The Artificial Production of Vigorous Trees by Hybridisation.** — HENRY, A., in *Quarterly Journal of Forestry*, vol. XIV, no 4, pp. 253-257, bibliography of 6 works. London, Oct. 1920.

For several years the author has been making experiments in the production of new trees by hybridisation, in the hope of obtaining fast-growing kinds that would produce timber rapidly (1). A considerable number of such trees have occurred accidentally, and among them may be mentioned the Lucombe Oak, the Huntingdon Elm, the Black Italian Popolar, the Cricket Bat Willow, and the London Plane. These all show the striking feature of first crosses in the difference of the rate of their growth from that of the parent species. These hybrids of the first generation, in trees as in other plants are remarkable for their size, rapid growth early and free-flowering, the ease with which they can be multiplied, and in all probability their comparative immunity from disease. Impressed with these facts, the author urged in 1910 that the artificial production of trees by crossing was a new and important field of research.

It is a popular belief that fast-grown timber is necessarily soft and comparatively worthless. This is a fact in most conifers; but in one class of broad-leaf trees, the wood of which is characterised by large pores in the inner part of the annual ring, the contrary is true, as the faster the timber of these trees is grown the stronger and denser it becomes. This class includes oak, ash, chestnut, hickory and walnut, the species in fact that, par excellence, produce the most valuable timber.

The difficulty of growing the ordinary species of oak, ash and walnut is the long period required for their maturity, which renders hopeless, except on the best soils, all chance of an adequate financial return. Without vigorous first crosses, the most valuable classes of timber can only be grown in limited quantity.

Immunity from disease might be expected in some, if not all, first crosses. In the case of ordinary species, individuals of great vigour are undoubtedly less liable than weaklings to the attacks of most fungi and are probably less sought after by insects like Chermes and Aphis. In this way, the Dunkeld hybrid Larch (*Larix eurolepis*, A. Henry) may prove immune to Dasyscypha. There is also a possibility of obtaining hybrids, capable of thriving on certain classes of soil, as chalk and peat, on which ordinary kinds of trees cannot be properly grown.

---

(1) See *R.* 1915, No. 31 (*Ed.*)

An important question is the propagation of these vigorous crosses once they are created. The first cross does not come true from seed and can only be multiplied by vegetative reproduction. This is easy when the trees are readily propagated by cuttings, as in the case of poplars and willows, or by layers, like the Huntingdon and Belgian elms. We may resort to grafting low on stocks, which should be seedlings of one or other parent.

No explanation has yet been offered in the author's opinion as to the real cause of the extraordinary vigour displayed by hybrids. The vigour is distributed over the whole plant, and is as conspicuous in the roots as in the stem and leaves. What we actually observe is not only an acceleration of, but also an increase of cell-division in all parts of the plant. The cells divide very quickly, continue to divide, and thus build up a taller stem, a more extensive root-system, etc. It is possible that the stimulus which causes growth (i. e ,cell-division) to commence and to continue is some soluble compound or enzyme. Whether the amount of vigour in hybrids is directly associated whith the degree of relationship between the individuals that are crossed is a disputable point, but one of pratical interest in the selection of parents for crossing experiments. One of the author's most vigorous hybrids *Populus generosa*, is derived from two parents so little related that they are placed in two distinct sections of the genus. A cross between two races of the common alder shows considerable vigour, though the parents can only be distinguished by the most trivial characters. The fact, if established, that different races when crossed give vigorous progeny could be turned to practical account in plantations and forests where natural regeneration is looked for. The introduction of a few lines of the Riga variety into a plantation of native Scots Pine might ultimately (as pollination would be effected by the wind), give seedlings of enhanced vigour.

The production of hybrid trees can be undertaken with the best chances of success in southerly stations, where numerous species happen to be cultivated. If hybridisation is tried on a commercial scale, lofty green houses and ladders will be required for the protection and easy handling of the flowers of many species.

Very little has actually been done in hybridisation of forest trees. KLOTZSCH started work in this direction in 1845 at Berlin. He crossed four pairs of species, all common trees (pine, oak, alder and elm), and after eight years the hybrids averaged one-third better than the parents. We next hear of artifiicial hybridisation of trees in California, the most notable being the production of the Royal and Pardox hybrid Walnuts, by BURBANK. The statements currently made in books about these are gross exaggerations; nevertheless, there was considerable increase of growth.

The original Royal Walnut, produced by a cross actually made in 1878, was measured by SHULL in 1907, and found to be 50 ½ ft. in height and 26 inches in diameter breast high. The authors experiments, carried out in 1909-1914, produced several interesting hybrids, the most remarkable being *Populus generosa*. Subsequent experiments in hybridisation carried out at Kew during the war have resulted in the production of numerous seedlings of ash from various crosses that were carefully made, the parent species being *Fraxinus excelsior, F. americana, F. pennsylvania* and *F. oregona*. In no case can one detect the slightest difference between the seedlings and the mother parent, and it seems then as if this is an example of what BATESON calls monolepsis (1). The occurrence of this phenomenon in *Fraxinus* is very embarrassing and would seem at first sight to put a stop to all chance of obtaining true hybrid ash trees. In nature, however, there are cases where hybrids occur, but occur with great rarity, the conditions for their production being unknown. In the case of the ash, the experiments ought to be multiplied and be carried out on a very extensive scale in some place where pollen of numerous species would be available. The author suggests Washington D. C. as the best locality.

The financial advantage of producing a hybrid ash is obvious, but may be simply illustrated as follows. Grant that on a certain soil the common ash attains the requisite size and suitable for felling at 70 years old, and that the hybrid ash, quicker in growth, equals this at 56 years old. Assuming the rate of interest to be 5 per cent which means the doubling of capital in 14 years, it will be readily seen that the hybrid ash in this case is twice as productive as the common ash. The doubling of the value, is an object worth considerable outlay in experiment, and in the author's opinion the artificial production of hybrid trees ought to be taken up seriously and arrangement be made for the establishment of a station for this research either in France or in the United States. This station might be internationalised.

41 - **The Electrification of Seeds by the Wolfryn Process.** — SUTTON, M. H. F., in *Sutton and Sons, Bulletin* No. 11 pp 1-7, Reading 1920 (2).

A series of tests were carried out with seeds of mangold, swede, cattle cabbage and carrot to compare the percentage of germination and the crop values from seed: — 1) Untreated (2 control plots); 2) treated by the WOLFRYN process; 3) immersed in salt solution; 4) immersed in sulphate of ammonia solution; in the two last cases, 4 oz., per gallon solutions and subsequently dried at a temperature of 100°F. The purpose of the experiment was to ascertain if the process is sufficiently beneficial as regards results to justify the expense entailed, and also if the benefit is due only to this process of if equally satisfactory results can be obtained through immersion alone.

---

(1) The most notorious example observed by BATESON was as follows: the orchid *Zygopetalum Mackayi* fertilised with pollen of various other orchids (*Odontoglossum* sp., *Lycasta* sp., *Oncidium* sp.), gave purely maternal plants. On the other hand, without pollination no seed is set so that *Z. Mackayi* is not pathogenetic. BATESON states that the conclusion cannot be avoided that fertilisation has acted as a stimulus to development without any admixture of paternal character. — See BATESON, W, *Mendels Principles of Heredity*, p. 248. Cambridge University Press, 1909. (*Ed.*)

(2) See *R.* June, 1919, No. 720. (*Ed*)

Germination Test. — Notwithstanding the one or two points which appeared slightly in favour of the electrified seed, the general results could only be regarded as inconclusive. The mangold seed (electrified) showed the highest germination, but was closely followed by the seed immersed in sulphate of ammonia solution. The untreated seed with carrot and cabbage stood first in the final results

Field Test. — On light loam on a gravelly subsoil; in 1918 dressed with farmyard manure and cropped with lettuces, endives etc; no manure in 1919. In this case also the mangold electrified seed gave the more marked result and a slightly higher yield than any of the other tests.

In no case was the plant from electrified seed observed to appear above ground in advance of the others. With regard to the other crops, reviewing the outdoor tests as a whole the results hardly appeared conclusive, the returns from the electrified seed showing no distinct advantage over the other sections.

42 - **Classification and Detailed Description of Some of the Wheats of Australia.** — *Commonwealth of Australia, Institute of Science and Industry,* Bulletin No. 18, p. 1-48. pl. 5. Melbourne. 1920.

Results of an investigations made concerning the classification of Australian wheats, which were subdivided into 16 classes, each class being distinguished by one of the following points: — bearded or beardless; pubescent or glabrous; dark chaffed or light-chaffed; dark grained or light grained.

Although 16 classes are theoretically possible, actually all the wheats here described are included in the following classes:

1) Bearded, glabrous, light chaffed, light grained.
2) » » dark chaffed, light grained.
9) Beardless, glabrous, light chaffed, light grained.
10) » » light chaffed dark grained.
11) Beardless, glabrous, dark chaffed light grained.
12) » » » » dark grained.
13) » pubescent, light chaffed, light grained

The majority belong to Classes 11 or 12. Each class is in its turn distinguished according to the following botanical and agricultural characters.

I. BOTANICAL CHARACTERS: 1) Solid or hollow straw at the 3rd internode from the head. Any variety in which the majority of the culms in a plant have a diameter of the central cavity less than half the diameter of the straw can be classed as a solid strawed variety; 2) character of awns: a good many wheats possess awns which are longer at the tip than those at the base; in some cases nearly all the spikelets may have short awns which are little more than acute beaks to the glumes and these are termed tip awned; 3) character of head: either clubbed, square or tapering. In the first case, the head, is broader and more dense at the tip than at the base ; in the second almost an equal breadth from tip to base and third; narrower at the tip ; 4) density of ear (number of spikelets per 100 mm. of rachis) three possible degrees of density can be recognised: *a*) dense type with any thing over 25 ; *b*) medium dense type 20 to 25 ; *c*) open type under 20 ; 5) spikelets: These vary in size and appearance, some being compact with the florets tightly packed together and the outer glumes pressed against the outer florets, while in others the rachilla to which the florets are attacked is elongated, causing the florets to spread and open out, and the whole spikelet to become fan shaped. The spikelets in the majority of Australian wheats can be described as medium spreading ; 6) number of grains per spikelet : the greatest number found is 7, but the usual number is from 4 to 5 while some varieties seldom have more than 2 or 3 ; 7) outer glumes : in some cases the keel is broad at the tip and practically disappears at the base while in others it is small, but is even throughout the entire length of the glume : the apex of the glumes varies from long to short, straight to curved, blunt to acute ; the presence or absence of a lateral point on the shoulder, which marks the termination of a large vein is usually characteristic for a variety : The following types of outer glume are found : — *a*) Keel even, bleak blunt no lateral point *e. g.* Federation ; *b*) keel even, beak long, distinct lateral point, *e. g.* Dart's Imperial ; *c*) keel broad at tip, beak long, blunt, slight lateral point, *e. g.* Roseworthy ; *d*) keel broad at tip, beak long acute, *e. g.* Bearded Gluyas; *d*) keel even, marked, beak small, distinct lateral point, *e. g.* Huguenot — 8) Grain. — Colour, size, shape and hardness are all susceptible to great variation, dependent to a certain extent on the season. Grains rich in gluten are translucent, whereas those rich in starch content are opaque ; a wet season will cause almost any grain to be opaque, the slow ripening inducing a large formation of starch, while rapid ripening in a dry, warm season produces a flinty, translucent appearance. Two distinct types of colour can be recognised : dark or red grained and light-grained. As to size, the smallest grain measured on an average 6.5 or 7 to 8 mm. The general shape is constant: blunt at both ends and square in outline ; length and breadth much the same ; long, narrow and pointed ; usually oval.

AGRICULTURAL CHARACTERS : — *Stooling property.* — Meteorological conditions have a considerable effect on stooling. This is evident according to the results obtained at Longerenong Agricultural College with the same varieties of wheat during the two seasons of 1912 and 1914. In 1912 the plants were above ground by the end of June and the rainfall was heavy up till the end of August ; while in 1914 there was less rainfall at seeding time and during the early stages of development. Some of the variations in stooling properties are as follows

	1912	1914
Federation	21	8
Firbank	18	11
Thew	16	9
Kubanka	21	9
Yandilla King	11	6
Huguenot	5	4

These figures show that it is useless to do more than describe a variety as a poor, medium or prolific stooler.

Season. — The division into early, mid season, and late wheats is based on the time of ripening of the ear. But although it is certainly a constant feature in a district with a fairly equable climate, such as is found in Victoria, this does not hold throughout the Commonwealth, with its widely varying climates. Wheat in a district with winter rain and a warm dry spring will tend to ripen much earlier than in a district with a cold dry winter and spring rains. In the first case the, varieties tend to ripen at much the same time, whereas in the second there will be more than a month's difference between the earliest and the latest varieties. This can also be seen in the same district in two different seasons.

These fluctuations are, however, considerably reduced, if the length of time elapsing between germination and full bloom is taken into consideration.

The following are some of the results obtained at the Roseworthy Agricultural Experiment Station, 1906-1908:

	Number of days between germination and ripening
Early varieties	179
Mid-season	198
Late	206

with a maximum difference of 27 days.

	Number of days between germination and blooming
Early varieties	132
Mid-season varieties	150
Late varieties	171

With a maximum difference of 39 days. The data collected by Prof. PERKINS of Adelaide are therefore confirmed as regards the advisability of taking into account the date of time of earing rather than the time of ripening before classifying as early or late. Although the time of heading is not in any case more than 14 days at the most, the variation in the time of ripening may be as much as 70 days. It has not, however, been possible as yet to collect lists from the different States as to the time of heading and the seasons here mentioned refer to the time of ripening.

Character of Early Growth. — Erect stems — as they appear above ground, develop vertically; this in striking contrast to the spreading type in which the stems lie horizontally. Between these 2 extremes, 2 intermediate types may be distinguished.

The following list includes the most important varieties grown in Australia divided up into classes and types according to the definite botanical characters and the more variable agricultural characters:

CLASS I. — *Type* 1: Bearded, glabrous, light chaffed and light-grained. *King's White.*
CLASS II. — *Type* 2: Bearded. glabrous, light chaffed, dark grained: *King's Red.*
CLASS III. — *Type* 3: Bearded, glabrous, dark chaffed, light grained: *Bearded Gluyas.*

CLASS IV. — Beardless, glabrous, light chaffed, light grained.

Type 4 : Head slightly clubbed, tip awned, straw hollow or slightly pithy, grain large : *Currawa, Penny, Dart's Imperial, Clubhead.*

Type 5 : Head square or very slightly clubbed, sometimes tapering, tip awned, straw hollow or slightly pithy, grain large. *Major, Wallace, Purple Straw.*

Type 6 : Head slightly tapering, tip awned, straw hollow or very slightly pithy, grain large : *Steinwedel. Roseworthy, Yandilla King, Farmer's Friend, Baroota Wonder, Bunyip.*

Type 7 : Head tapering, tip awned, straw hollow or slightly pithy, grain small : *Queen Fan.*

Type 8 : Head tapering, tip awned, straw hollow but with slight pith, grain large : *Triumph, Majestic, Genoa, Florence.*

Type 9 : Head tapering, tip awned, straw hollow, pithy, grain large : *Marshall's No.* 3, *Rymer, Firbank, Caliph.*

Type 10 : Head tapering, bald, straw very pithy almost solid, grain large : *Warren.*

Type 11 : Head tapering, bald, straw hollow, grain large : *New Zealand.*

Type 12 : Head tapering, bald, straw hollow, grain small : *Comeback Jonathan, Bobs.*

CLASS V. — Beardless, glabrous, light chaffed, dark grained.

Type 13 : Head tapering, tip-awned, straw hollow but pithy, grain small : *Marquis.*

Type 14 : Head tapering, bald, straw hollow, grain large : *Warden.*

Type 15 : Head tapering, bald, straw hollow, but slightly pithy, grain small. *Cedar.*

CLASS VI. — Beardless, glabrous, dark, chaffed, light grained.

Type 16 : Head square, almost clubbed, tip awned, straw hollow, grain large : *Bayah.*

Type 17 : Head slightly tapering, tip awned, straw solid, grain large : *Gluyas, Canberra.*

Type 18 : Head slightly tapering, bald, straw hollow, grain medium. *Federation, Hard Federation.*

Type 19 : Head tapering, slender, tip awned, straw hollow, grain large : *John Brown.*

Type 20 : Head tapering, bald, straw hollow, but pithy, grain small : *College Eclipse.*

CLASS VII. — Beardless, glabrous, dark chaffed, dark grained :

Type 21 : *American* 5.

CLASS VIII — Beard less, pubescent, light chaffed, light grained.

Type 22 : *Jumbock.*

All these wheat varieties are common and *Federation* only represents 75% of the total production. Durum wheats are far less common, these are :—

CLASS I. — *Type* 1 : Bearded, glabrous, light chaffed, light grained : *Kubanka.*
CLASS II. — *Type* 2 : Bearded glabrous, dark chaffed, dark grained : *Medeah.*
CLASS III. — *Type* 3 : Beardless, glabrous, dark chaffed. light grained : *Huguenot.*

The author gives a detailed description of each variety accompanied by plates and figures. The following are the data relative to the origin of each variety :

1) *King's White*? Selection by Roseworthy Agricultural College from Joseph King's King's Early.
2) *King's Red* : Selection by Roseworthy Agricultural College from Joseph King's King's Early.
3) *Bearded Gluyas* : Appeared as a sport in Roseworthy Agricultural College, Gluyas selection plots.

4) *Currawa* Hybrid obtained by H. Pye by the following crosses:

Northern Champion × Cretan
Little Club × Unnamed
Currawa

5) Penny: Slection from Squarehead, produced by Penny, Green Hills, Western Australia.
6) Dart's Imperial: Selection from an unknown variety produced by T. Dart of Nhill.
7) Clubhead: (= California Club, Oregon, Chili, Little Club): imported from the United States
8) Major: Federation × Wallace Bred by H. Pye of Dookie.
9) Wallace: Purple Straw × Fife Indian Bred by H Pye.
10) Purple Straw: Unknown.
11) Steinwedel: Selection from Champlain's Hybrid of Dalkey, South Australia in 1886.
12) Yandilla King: Yandilla × Silver King. Bred by R. Marshall of South Australia.
113) Roseworthy: Received by Roseworthy Agricultural College from Farrar in 1902 as Jonathan. It was grown there for some time, but in 1913 it was found to be quite different from the original Jonathan, and it was therefore renamed Roseworthy.
The hybrid Jonathan was apparently sent in an unfixed condition.
14) Farmer's Friend: Selection from Purple Straw, by John Johns, of Katandra, Victoria.
15) Baroota Wonder: Selection probably from Ward's Prolific by G. Crittenden, Telowie, South Australia.
16) Bunyip: obtained by the following Crosses.

Blount's Lambrigg × Hornblende
Purple Straw × Improved Fife King's Jubilee × Unnamed
Rymer × Maffra
Bunyip

17) Queen Fan: Fan × Carmichael's Eclipse Cross-bred produced at Roseworthy Agricultural College.
18) Triumph: Silver King × Rangit. Bred R. Marshall, South Australia.
19) Majestic: election from Ward's Prolific by R. Marshall.
20) Genoa.

White Naples × Improved Fife.

Unnamed × Lambrigg's Australian Talavera
John Brown

Bred by W. FARRER

41) College Eclipse : Selection from Carmichaels Eclipse, made at Roseworthy College.

42) American 8 : Imported from America.

43) Jumbuck :

Fife × Tardent's Blue
Unnamed × Australian Talavera
Jumbuck.

Bred by W. FARRER.

DURUM WHEATS

44) Kubanka (= Belotourka) : Obtained from Kazan Kerghiz Steppes, Russia.

45) Medeah : obtained from M. VILMORIN, Paris.

46) Huguenot : produced by A. CORRELL, of South Australia, selection from Medeah.

43 - **The Wheats at the Paris Seed-Testing Station.** — SCHRIBAUX, in the *Journal d'Agriculture pratique*, Year LXXXIV, No. 35, pp. 176-177. Paris, August 26, 1920.

In the experiment field of the Paris seed Testing Station, 4 varieties of wheat attracted special attention in 1919-1910. These were as follows:

(1) *South Tunisian Touzelle*. Ears 12 days before the Provence Tonzelle, is more resistant to lodging, and quite as productive. Does werll in South France, Tunisia, Algeria, and Morocco.

(2) *Carlotta Strampelli* (1). Grain of good quality, less resistant to rust than Rieti, but is more productive than the latter. Resists lodging. Can compare with some of the best northern varieties,

(3) and (4) *Vuiteboeuf* and *Bretonnieres* (2). Early productive, grain of good quality, very resistant to cold.

44 - **The New "Peace Hybrid Wheat".** — GANDOT, G in the *Journal d'Agriculture pratique*, Year 84, No 1, p. 298, 1 fig Paris, October 7, 1920

Messis VILMORIN-ANDRIEUX have just put on the market a new wheat the "ble hybride de la paix", obtained by crosses effected by P. DE VILMORIN.

This new hybrid is a descendant of the "blé hybride hâtif inversable" (early non-lodging hybrid wheat). Its other ancestors are Bordeuax wheat and one of the old Vilmorin hybrids. Its height is that of the "early non-lodging variety; its straw is stiff and strong, and glaucous before maturity. The ear is large, dense, red, and nearly square. The grain is large, yellow, and of clearly superior quality to that of the early "non-lodging hybrid".

This new wheat has been tested in several farms in the Paris district, where its yield has been roughly equal to what of the "early non-lodging hybrid". It belongs to the series of alternative wheats. When sown in autumn it is slightly later than the "early non-lodging". In the spring it can be sown up to the middle of March and grows very well under these conditions.

45 - **Early Varieties of Wheat and Oats.** — SÉVERIN, R., in the *Comptes rendus de l'Académie d'Agriculture de France*, Vol. VI, No. 25, p. 640. Paris, July 7, 1920.

With the idea of completing, in the order of ripening, the series of early wheats that are rust-resistant in the climate of the Gironde, the author presented to the Académie, after Pusa N°. 4, Hindi, and Pereal Toti, type ears of 3 varieties of the same order and suitable to arid soils of average fertility and to the rudimentary methods of dry-farming, as these wheats can grow with as little as 300-350 mm. of rain. These wheats are of average productiveness and are adapted to producing early crops, for they ripen earlier than rye and all the native wheats (semi-winter), or to extra-late spring-sowing, when the crop ripens at the same time as autumn wheats. They can also be grown in summer, in order to compensate for any deficiencies in the normal harvests by a new autumn crop. They are as follows: —

(2) See *R.*, Nov-Dec., No. 1090. (*Ed.*)

(1) Awnless "Cedar wheat," of Hindoo origin, selected by the Agricultural Station of Berkeley, California. Its straw is short, fine, flexible, resistant to lodging, and the red, glutinous, grain is characterised by a dorsal furrow.

(2) Awned "Propo" wheat, of very vigorous growth, strong tillering and regular yield. Its narrow leaves, fine flexible straw that bends under the weight of the ears, all contribute to form the pendent tufts that characterise its habit The grain is whitish, and gives a lemon flower much prized for fancy-baking and pastry-making.

(3) Chinese wheat (introduced by VERSIN of Orleans in 1918) has an awned, cylindrical ear, which is short and blunt, and packed with coloured grain emerging from the glumes; the grain is dry and semi-glutinous This variety is characterised by such a capacity for tillering that it may be said to bear two crops a year.

The author subsequently presented 2 samples of awnless, SCHRIBAUX Ligowo × Brie oats (1) .The Ligowo × Brie oat cultivated in Gironde has no awns, as has been found on growing it is summer and spring for two years. He also showed the "Liberty" variety of oat, which was obtained by Prof. SAUNDERS (Cerealist of the Dominion of Canada). It is awnless, which makes it much in request by the oatmeal industry, and, in addition, very early.

46 - **Relative Yields from Broken and Entire Kernels of Seed Maize.** — BROWN, E B, in the *Journal of American Society of Agronomy* Vol 12, Nos 6-7, pp. 196-197 Washington, C. Sept-Oct, 1920

Investigations were carried out in 1914 to discover whether injuries of a physical nature to kernels of seed maize affects the growth, development, and productivity of the plant. Broken or cracked kernels from each ear were planted in comparison with uninjured kernels from the same ear. The breaking was similar to the injuries that frequently occur in mechanical shelling and seeding. The injuries were confined to the endosperm, in no instance extending to the germ.

The following shows a comparison between the relative yields obtained:

Class	Adult plants	Ears produced	Total weight of ears	Ears per plant	Average weight of ears	Yield per plant	Yield per acre
					lb	lb	bus
Broken seed .	57	57	36 5	1 000	640	640	64 0
Entire seed .	78	77	55.4	988	616	716	71 1
Difference . . .	—	—	—	—	—	—	7.6

---

(1) See *R*, May, 1920, No 507. (*Ed*)

Based on 7 000 plants per acre and 70 lb., of ears to the bushels.

The field germination from the broken seed was less than from the entire seed, and the seedlings were weaker. The general height of plants at maturity did not materially differ. In number of ears per plant the increase in number of ears from the broken seed was associated with the increased space per plant resulting from the poorer stands. The weight of ear and yield per plant was consistently less than that from the entire seed.

In practical maize growing the losses in yield per acre from broken seed would be much less and frequently negligible, but the tendency would be the same.

47 - **Cultivation and Uses of Buckwheat in the United States.** — LEIGHTY, E (Agronomist in Charge of Eastern Wheat Investigations), in the *United States Department of Agriculture, Farmers' Bulletin,* 1062, pp 3-24, figs. 6. Washington, D. C, Oct., 1919.

A detailed account is given of the climatic requirements, soils most suitable, the general cultivation from sowing to harvesting, the thrashing methods employed and the yields. Buckwheat is grown principally in the north-eastern part of the United States, more than 60 % of the crop being produced in New York and Pennsylvania. The area production and farm value (1) 1904-1908, inclusive is shown as follows .

Year	Acre	Average yield per acre	Production	Average value per acre
Annual average	acres	bushels	bushels	dollars
1904–1908.	789 000	18.86	14 880 000	12.32
1909–1913.	843 000	19.71	16 616 000	13.73
1914–1918.	870 000	17.76	15 360 000	20.61

The legal weight per bushel is 48 lb., in the States where most of the crop is produced, but varies according to the different States.

This crop has been found to succeed well on acid soils, and on poor land. It serves to make even very hard land mellow and friable. Consequently it is a good crop to use in preparation for such crops as potatoes etc. It does best where the climate is cool and moist.

Uses. — It is estimated by the United States Department of Agriculture that on an average, 7 bushels (48 lb. each) yield 1 barrel (196 lb.) of flour, *i. e.* a yield of 58 $^1/_3$ %. Buckwheat more than one year old is reported to make flour inferior to that made from new grain. The grain contains in each 100 lb., 10.8 lb. crude protein (about the same as maize), 72.5 lb. carbohydrates, and 2.5 lb. fat.

The whole grain is a source of food and feed and it makes a good poultry feed. The straw is also sometimes used and is more readily eaten by the stock if well preserved.

---

(1) See *R.*, March 1917, Nos. 215 and 258. (*Ed.*)

Further uses of buckwheat are enumerated as follows: — weed destroyer, green manure and soil renovator, e. g. sowing with rye has been found advantageous, an orchard cover; a honey plant.

48 - **Hairy-Vetch Seed Production in the United States.** — KEPHART, L. W. (Scientific Assistant) and MACKEE, R. (Assistant Agrologist, Office of Forage Crops Investigations). in *U S Department of Agriculture, Bulletin*, No 876, 32 p, figs 7 Washington, D. C, September 1, 1920

"Hairy vetch," also termed "Russian vetch," "sand vetch" and "winter vetch" (*Vicia villosa*) is a hardy winter-annual legume, with wide adaptations to an unusual variety of conditions and uses. It thrives in nearly all soils and climates and is probably more widely distributed than any other leguminous forage crop except sweet clover. It is grown for hay, pasturage, soiling, green manure, a cover crop, silage and seed. The plant is especially noteworthy for its ability to grow on poor soil, for its resistance to cold, drought, and alkali; and for its comparative immunity from insects and diseases. There qualities have led especially to the use of the plant for building up poor soils and as a substitute for red clover, alfalfa, and the grasses in regions where these crops do not flourish. Hairy vetch has thus come to be considered as essentially a poor-land crop. It is equally valuable on richer soils, however, and can be used to advantage in any system of farming where a winter-growing forage crop is desired.

The consumption of hairy vetch seed in the United States increased about twenty-fold in the 5-year period from 1908 to 1913, and the crop is now grown in some part of nearly every State. Nevertheless, hairy vetch has not met with the general popularity that its good qualities would seem to warrant.

A common objection to hairy vetch is that the plant is a weak-stemmed vine which is unable to stand upright withont support. Unless accompanied by a companion crop to which it can cling, it is apt to lodge badly and to make a heavy tangled masswh ich is difficult to plough under or to harvest But the high cost of seed has been the greatest handicap to its more extended use.

In the past, large quantities of hairy-vetch seed have been imported in the United States (4 547 824 lb., in 1913), but in more recent years this quantity has been greatly reduced (256 500 lb., in 1919). The reduction in imports resulting in the high price of seed, has lent interest to home production.

Michigan has been the principal centre for the production of hairy-vetch seed, but seed production has proved successful in practically all localities where the crop can be grown.

Hairy vetch is adapted to a wide range of soil types, but it does best on rich sandy loams.

The crop can be seeded, harvested, and thrashed with ordinary farm machinery with but little or no modification.

The seed of hairy vetch is difficult to separate from the small grains with ordinary seed separators, but the spiral separators now used in many localities have proved successfull.

Diseases and Insect Pests. — Until quite recently hairy vetch was considered almost immune from the attacks of fungous diseases and insects. But little work has been done in the matter of identifying and determining methods of control for the diseases of hairy vetch. A leaf spot disease (*Mycosphaerella pinodes*) attacks the leaves of hairy vetch quite frequently and does some damage. Another disease (*Protocoronospora nigricans*) which attacks the stems, leaves and pods, has done considerable damage to hairy vetch and has been especially serious the past few years in the South Atlantic States. No control measures have been worked out for either disease.

One of the few insects that injure hairy vetch to any extent is the pea aphis (*Macrosiphum pisi*), which attacks the plants during the blossoming period and sucks the juices from the stems and leaves just as the seeds are setting. In wet seasons and in heavy rank growth the aphids sometimes appear in great numbers and almost destroy the vines before their presence is suspected. Fortunately, aphids cause much less damage in the thin, open stands which are the most profitable for seed production. The injury from aphids is most likely to occur on heavy soils where the crop is grown for hay. No practical means of control is known.

In the cotton belt, especially along the Atlantic coast, hairy vetch occasionally is injured seriously by the common cotton bolloworm (*Chloridea obsoleta*). The invasions of this insect, when taken in time, are easily combated. They are most likely to occur during the spring months before the other host plants of the insects are available for food. Where the cotton bollworm attacks hairy vetch, the most useful remedy is to apply the following mixture as a spray at the earliest possible moment viz powdered arseniate of lead 1 lb. + water 50 gal. Where this poison is used at the strength specified, there is comparatively little danger of poisoning cattle. It is advisable, however, not to pasture vetch that has been sprayed with this mixture until after heavy rains have occurred.

49 – **Lespedeza as a Forage Crop.** — Carrier, L. (Agronomist, Office of Forage Crop-Investigations) in *Farmers' Bulletin*, 1143. *United States Department of Agriculture*, pp. 3-15 figs. 5 Washington, D. C, Aug 1920.

Lespedeza striata, commonly known as "Japan Clover" is one of the most valuable forage crops for the southeastern part of the United States. Its widespread adaptation to grazing conditions gives it an extraordinary value and will grow in open woodlands, on the forest of upland hills, along roadsides and in other waste places. Although an annual plant, sufficient seed is produced even under close grazing to reseed itself. As a legume, this crop has been found valuable for soil improvement, and is also relished by all classes of livestock. Results show that good hay is produced on alluvial bottom lands, and wherever sufficient growth is made for cutting for thus purpose, lespedeza is recommended for use in crop rotations. A 3-year rotation of maize, oats and lespedeza is advised in preference to only oats and lespedeza. The last is often allowed to stand a fourth year, and cow peas should be planted in the maize as the last crop. Wherever this system is followed, there is a marked increase in yield as for example, in Mississippi and Louisiana.

Oats may be harvested and a crop of lespedeza either for hay or seed grown on the same land in one season.

The chief use recommended is as a constituent in permanent pastures of Bermuda grass (*Capriola dactylon*) and carpet grass (*Axonopus compressus*) An abundance of moisture is required for maximum growth, but good drainage is essential, as the plants will not succeed on wet land.

Details are given by the author with regard to the history, distribution and cultivation, and use in meadow mixtures.

50 - **Perennial Ryegrass and Wild White Clover.** — GILCHRIST, Prof., in *The Journal of the Ministry of Agriculture*, Vol. XXVII, No. 7, pp 671-677. London, Oct 1920

A lecture emphasising three important points in grassland improvement: (1) The benefits following the inclusion of wild white clover (*Trifolium album*) in seed mixtures; (2) the value of perennial rye grass and the proper method of retaining and devoloping this grass; (3) the improvement of turf which results from proper treatment of grass

I. — After many years experience the mixture used for three-year leys on poor clay with excellent results was as follows:— 16 lb., perennial rye grass, 10 lb., cocks foot (*Dactylis glomerata*), 4 lb., timothy (*Phleum pratense*) 4 lb., late flowering red clover, 1 lb., trefoil and 1 ½ lb., wild white clover per acre The rotation was a six course one and since 1912, five of the 3-year leys were reported as producing in the first, second and third years, 42 cwt., 45 cwt., and 38 cwt., per acre respectively. The unusual results were said to be due to the inclusion of the white clover.

The clover aftermaths were found most valuable for grazing and inconsistently good condition, and the turf at the end of the 3 years was always excellent.

On poor stiff clay soil of low value an addition of 4 lb., wild white clover gave an average crop of hay for eleven years of 34 cwt., per acre compared with 23 ½ cwt., without this addition.

With, regard to the treatment of the leys, a good seed bed is advocated as being of the greatest importance. The only manure used throughout the whole experiment was 10 cwt., per acre of basic slag. This was applied to the young seeds as soon as possible after the barley crop was harvested on the 3-year leys, and every third year on the above mentioned poorer soil.

The inclusion of late flowering red clover in the mixture was due to clover sickness to which the ordinary red clover is more readily addicted.

II. — The lecturer explains that previous failure with perennial ryegrass was due largely to the absence of close grazing and heavy treading by stock. Several instances are quoted showing that by paying due attention to these two points. the more nutritious will be the pasture and the more numerous the head of grazing stock which it will carry.

To illustrate the improvement of turf which follows the treatments outlined, specimens indicated that: (1) Unmanured turf consisted mainly of poor wiry bent fescue grasses, stunted and starved wild white clover plants, and 2 inches of dead organic matter, and underneath an apparently worthless soil; (2) treated with basic slag and closely grazed with cattle showed instead an abundance of perennial ryegrass and other good grasses, and a luxuriant growth of wild white clover. The subsoil was a good sandy loam, dark in colour with rich organic matter and moisture.

51 - **Effect of Mole Tunnelling on the Flora of the Pastures of Cantal.** — URBAIN, A. J. and MARTY, P., in the *Comptes rendus de l'Académie des Sciences*, Vol. CLXXI, No. 13, pp. 581-583. Paris, Sept. 27, 1920.

The unmown meadows of Cantal (Auvergne, France), particularly those in the higher districts are covered with mole-hills, which are soon over-run with abundant vegetation. The authors have made a special study of the flora of these mole-hills and have followed up its development.

The following Table gives the species found during the first first two years of research on mole-hills in a damp meadow in the neighbourhood of Aurillac: -

FIRST YEAR.

Usual meadow plants.	*Ranunculus acris* L., *Ranunculus bulbosus* L., *Trifolium repens* L.. *Hieracium Pilosella* L., *Rumex Acetosella* L., *Juncus effusus* L.
Plants not habitually present. .	*Lotus corniculatus* L., *Trifolium pratense* L., *Cirsium acaule* All. (rare), *Cichorium Intybus* (rare), *Veronica serpyllifolia* L., *Ajuga reptans* L.

SECOND YEAR.

Usual meadows plants	*Ranunculus acris* L, *R. bulbosus* L., *R. Flammula* (rare), *Trifolium repens* L, *T. montanum* L. (rare), *Potentilla verna* L., *Achillea Millefolium* L., *Taraxacum Dens-Leonis* L., *Hieracium Pilosella* L., *Gentiana Pneumonanthe* L. (rare), *Myosotis palustris* With (rare), *Rumex Acetosella* L., *Juncus effusus* L., *Luzula campestris* D. C., *Carex vulgaris* Fries, *Nardus stricta* L., *Anthoxanthum odoratum* L. (rare), *Phleum pratense* L., *Poa pratensis* L., *P. trivialis* L., *Agrostis alba* L.
Habitually present.	*Polygola vulgaris* L., *Lotus corniculatus* L., *Trifolium pratense* L., *Vicia Orobus* D. C. (rare), *Potentilla reptans* L., *Galium verum* L. (rare), *Cirsium acaule* All. (rare), *Calluna vulgaris* Salisb., *Plantago lanceolata* L., *Holcus lanatus* L., *Polytrichum commune* L.

The effect of the network of mole-tunnels is:—

(1) To drain the soil.

(2) To carry out a kind of ploughing and harrowing at many points on a level with the mole-hills, thanks to which the natural meadow seeds,

as well as those brought by wind and birds, can germinate easily and fight successfully against the encroaching native vegetation.

(3) To introduce new plants, sometimes good fodder types, such as *Lotus corniculatus* L., *Trifolium pratense* L., *Holcus lanatus* L., etc.

52 – **Cotton in South-West Madagascar.** — JUMELLE, H., in the *Comptes rendus des Séances de l'Académie d'Agriculture de France*, Vol. VI, No. 32, pp 784-788. Paris, Nov. 3, 1920.

Some fifteen years ago cotton cultivation in north-west Madagascar gave some hopes of success, but now it is in a very neglected condition.

It is a long time since the cotton-plant grew in a semi-wild state in many parts of the island, in the centre, north-west and south, and the natives have cultivated it for a very long time.

From the climatic point of view, taking the animal rainfall, as a basis, the zone where cotton is grown comprises $^4/_5$ of the total area of the island i. e., the western, north-eastern towards Antalaha, and the High Plateaux regions, but, owing to soil conditions the area of importance as regards the crops is much reduced and part of the centre in particular appears to have been eliminated.

Damage due to insects and other pests have discouraged those who first took up cotton growing, so much so that it will not be easy to urge that the former attempts be renewed.

In case the opinions should be modified or where it appears the right moment to start experimenting again, neglecting the American varieties, for example, as being too delicate, and replacing them with more robust types such as the improved forms of species long since acclimatised to the island, and if the industry will accept these cottons, it will be useful to know which are these types which have remained.

Judging from specimens sent by M. PERRIER DE LA BÂTHIE to the author, and which he considers as corresponding to the type that grows wild at the present time, but has never been cultivated in any of western villages this "native" Madagascar cotton is *Gossypium purpurescens*. The designation "native" is used because it was introduced into Madagascar and naturalised a long while ago. It is not unlikely that *G. taitense*, might be found as frequently, as this species is so closely allied to the aforementioned type that they might be confused one with another, when their distinctive characteristics are not property known; in every case, the author's specimens are certainly closer to *G. purpurescens* than to *G. taitense*.

The Mahafaly natives in south-west Madagascar cultivate a cotton which is also occasionaly semi-wild and is very close to *G. obtusifolium* ("cottonier de Bourbon", or "de Porto-Rico"), It has short hairs $^3/_4$ to 1 inch in length, and is very resistant to drought and the attacks of Rhynchota. *G. obtusifolium* comprises the Indian *Wightiana* variety, widely cultivated in India under the name of Gujarat cotton and classified as long staple; this is popular.

The author concludes that there is probably little reason for paying much attention to the Madagascar "native" cotton (*G. purpurescens*), but states that if and when the experiments are revived, it would be advisable not to attempt to improve the Mahafaly but rather to see what could be done with plants from seeds of the related Guyarat variety, which, although it has more or less degenerated owing to bad cultivation, is apparently the best suited to certain regions of west Madagascar.

53 - **The Seeds of "Sang Mau Bung" (*Horsphieldia Irya* Warb).** — VERNET, G. and NGUYEN-VAN-LONG, in the *Bulletin agricole de l'Institut Scientifique de Saigon*, Year II, No. 10, pp. 297-299 Saigon, Oct., 1920.

The Sang Mau Bung " tree (*Horsphieldia Irya* Warb, Fam. Myristicaceae) is fairly common in Cochin-China. The bark contains a red tanniferous latex which is used by the natives for throat troubles.

From the fresh grain BUSSY, using a hydraulic press, extracted an oleo-resin. Nothing was obtained by the authors from the ripe, dried grain when pressed, either hot or cold. When treated, with 90° alcohol, a resin was easily extracted which was quite suitable for making varnish. In making varnishes, 30 % of resin is dissolved in denatured 90° alcohol. When giving a first coat to wood, the varnish can be diluted with an equal volume of alcohol. After application with a brush and drying, the surface is very brilliant, but further coats must not be given till the previous one is dry.

As its melting point is somewhat low (120°C.), the varnish must not be exposed to higher temperature, as it loses its brilliance and becomes dull.

It is insoluble in water and MAGEN has used it for varnishing leather as it is sufficiently supple not to crack when the leather is bent in certain ways.

54 - **Change-Over Tappings of Hevea in Cochin-China.** — GIRARD, E., in the *Bulletin de l'Association des Planteurs de Caoutchouc*, Vol. VII, No 10, pp. 336-338 + 1 photo. Antwerp, Oct., 1920.

All sectors of the Suzannah and An-Loc plantations which have been tapped alternately have amply confirmed the results of the first experiments (1).

The alternations of tapping varied from one day in two to 1 ½ months in 3. The highest yields were always obtained, up to a certain limit, with the longer periods of consecutive tapping and rests. From the data obtained, the author has deduced, at least provisorily and applied to all the plantations the following rules for alternation: —

The first cut, 27.5 inches from the ground, should embrace $^1/_3$ of the girth. If tapping is made 6 days a week for one month in two the strip of bark should last at least 2 years and most probably 30 months. This allows over 6 or 7 years before it becomes necessary to work on the newly formed bark which undoubtedly forms more quickly and completely with alternate tapping. Under these conditions, each worker taps two parts in alternate months which corresponds, for each tree, allowing for Sundays and holidays, etc., when no work is done, to about 23 days of tapping out of 60 days, there being 37 days (30 consecutive) of rest for the trees. The system was applied first in August, 1919, and in December, 1919, the author found, for 26 days of tapping, an increase in yield of 85 % over the corresponding production in December 1918, for 31 days when the same plots were tapped daily. Full confirmation of this was obtained in August, 1920, a year after the inception of the system. The author points out the advantages that would result from the general adoption of the system.

---

(1) See *R.*, Jan., 1920, No 50, and *R.*, Sept, 1920, No. 980. (*Ed.*)

The application of the alternation of periods, which the author believes is necessary for the conservation of the rubber plantations (for its has been proved that daily tapping rapidly exhausts the trees), appears to correspond to a reduction of 30 to 40 % of the total crop during the first year. This decrease, however, is noticeable chiefly during the first few months. The result is to make the market less congested and after a very short time brings about a rise in prices.

Taking into account the large area of the plantation that has been tapped intensively for several years, two years must be allowed before full production is again reached after monthly alternation has been put into practice. This is a sufficient length of time for all the rubber produced by the plantations to be completely absorbed by the market.

55 - **Natural Coagulation of Hevea Latex in a Closed Vessel after the Addition of Calcium Salts.** — SPOON, W., in the *Mededeelingen van het Central Rubberstation*, No. 21. Buitenzorg, May, 1920. Translated into French by BRIANT, J., in the *Bulletin agricole de l'Institut Scientifique de Saigon*, Year II, No 10, pp. 308-310. Saigon, Oct. 1920.

In this work, the author gives detailed information on the acceleration of the natural coagulation of hevea latex by soluble calcium salts. He states that from 0.05 to 0.10 % (or 0.02 to 0.04 % of lime) of calcium chloride ($CaCl_2$) will bring about complete coagulation in a closed vessel in 24 hours.

WHITBY, CAMPBELL, and BARROWCLIFF think that this accelerating effect is due to an increase in the activity of the coagulant enzymes, but EATON is of the opinion that the action is purely chemical. VERNET (1) suggests that calcium salts have a coagulative effect on the latex proteins and thus lead to the coagulation of the latex.

The author also examined the influence of the winter on coagulation. During the dry season of 1919, the loss of leaves on the trees in the Experimental Garden at Buitenzorg was very pronounced and began at the beginning July of just before winter was over, i. e., at the end of August; the trees had already produced new leaves. The author found that in May and June the coagulation, always practically complete in 20 hours, was strong and the serum clear; during July, there was a change however, and coagulation remained very incomplete until the end of August. In September, it was completed within 20 hours.

As regards the trees in question, and the two cuts given on ¼ of the girth, it appears that a relation exists between winter and natural coagulation in the absence of air.

---

oct, 1920, No. 979. (*Ed.*).

It is possible, by employing special methods, to obtain complete and spontaneous coagulation within about 24 hours, by adding 0.2 % of sugar and keeping the mixture at a temperature of 40°C. (1) for 7 or 8 hours In the tests descibed here $CaCl_2$, was used. These agents give excellent results with latex during the wintry weather, in July and August, a period when spontaneous coagulation is incomplete. It is sometimes necessary to increase the quantity of sugar by 2 to 3 gm. per litre or the $CaCl_2$ by 0.5 to 1 gm. per litre of latex.

Some authors consider that calcium salts used in small quantities, are absorbed by the coagulum and may affect the rubber, but the authors experiments seem to show that the occlusion of $CaCl_2$ has no harmful effect on the rubber.

More rapid vulcanisation is obtained with rubber coagulated with calcium salts than with acetic acid, but the uniformity in the typical time of vulcanisation of crêpe treated with calcium salts is not as good as that of other naturally coagulated crêpes.

56 - **Influence of Large Cuts on the Chemical Composition of Hevea Latex.** — ARISZ, H. (after researches by SCHULTZ VAN VLISSINGEN, L. R. E. (Chemist at the Experimental Station of Besoeki), in the *Bulletin agricole de l'Institut Scientifique de Saïgon*, Year II, No. 10, pp. 311-312. Saïgon, Oct., 1920.

The following observations were made on the results of heavy circular cuts reaching the wood:—

(1) Independantly of the rubber content of the latex, the relation between the resinous matter and the rubber does not change.

(2) During the first fortnight, the concentration of organic substances in the serum does not change; after that it diminishes (2).

(3) The nitrogen content of the latex remains steady during the first few days and then decreases by one half. This loss is slightly greater than that of rubber; calculated on the percentage of rubber as well as on the latex; a decrease in the nitrogenous substances is evident in both cases.

(4) The concentration of the organic substances in the serum (more diluted and probably absorbed by the rubber) remains practically constant.

57 - **" Chicle " and the Exploitation of the "Zapote" (*Sapota Achra*) in Mexico.** — Communication from the National Office of Foreign Commerce (Office national du Commerce exterieur), in *L'Agronomie Coloniale, Bulletin mensuel du Jardin Colonial*, New Series, Year V, 1920-1921, No. 33, pp. 73-79. Paris, September, 1920.

The product sold under the name of " chicle " consists of a gum extracted from " chico zapote " (*Sapota Achras*, Fam. *Sapotaceae*), a tropical tree which attains the height of 20 to 25 m., and a girth at the height of a man of from 2.50 to 3 m.

---

(1) See *R.*, Oct., 1920, No. 979. (*Ed.*)

(2) This was first reported in the *Bulletin économique de l'Indochine* in 1905, No 44, p. 720, in an article entitled L'*Hevea brasiliensis*, sa culture et son exploitation dans Sud-Annam by M. G. VERNET. (Note by the Editor of the *Bull Agr. de l'Institut Scient. de Saïgon*).

The rugged cortex of *S. Achras*, when between 30 and 40 years of age, is 4 to 5 cm., thick. In Mexico, the flowering season lasts from March to May, and the fruit ripens from May to the end of September.

Hitherto, chicle has only been used for chewing, a common habit in the United States, and widely diffused in Europe since the war.

The wood of *S. Achras*, reddish or dark rose-coloured, and very hard, is used as timber, in carriage-building, and ship-bulding.

The tree thrives on the clayey, very damp soils of the coast, and does specially well on flat, low-lying ground. It also grows satisfactorily on calcareous soils.

The latex (chicle) is secreted by laticiferous cells, in which it occurs in the form of small whitish drops. These cells are situated in the part of the cortex nearest to the sap-wood. The latex flows through intercellular canals. The parts of the tree yielding most latex are the trunk, principal branches, and the secondary branches.

For a *Sapota* to yield the maximum amount of gum, it must, be growing on flat ground with a southern exposure, and in the neighbourhood of a stream or of a large body of water. It also requires a very heavy rainfall of long duration. The cold rains brought by the north winds prolong the season of gum-collecting so that it lasts to February or March, which is a great boon to the industry.

In Mexico (Yucatan), the latex is collected as soon as the tree has attained a girth of 80 cm., at 1.50 m., from the ground. The extraction begins with the first rains of the season, i. e., in July or August

A description is given of the implements used for obtaining the latex and preparing the gum. A man slowly ascends the trunk making, as he goes, a slanting incision with his " machete " from below upwards. At the lower end of the cut, he places a leaf to direct the latex, into a vessel at the foot of the tree. A clever " chiclero " can tap as many as 15 to 20 trees daily.

As soon as a sufficient amount of latex is obtained, it is stirred quickly with a stick, and then placed on the fire in small copper or iron pots. The latex must be constantly stirred to prevent it adhering to the sides of the pots and burning and to induce the evaporation of the water it contains. After having been sufficiently cooked, it is removed from the fire and allowed to cool before making it into blocks, by pouring it into wooden moulds that have been first placed in soapy water to prevent the gum from sticking to them. As soon as the gum is sufficiently cool, it is turned out of the moulds. The blocks thus made, weigh from 11 to 12 kg. The chicle gum is then sent to the ports to be shipped abroad, where it is refined, and placed on the market under the names of " pepsin gum ", " chewing gum ", " sen-sen gum ", etc.

58 - **The Cultivation and Distillation of Peppermint in Piedmont.** — MICHELETTI, C., in the *Bollettino dell'Associazione italiana Pro piante medicinali, aromatiche, ed altre utili*, Year III, No. 9, pp. 132-135. Milan, September, 1920.

Peppermint is grown in Piedmont in the neighbourhood of Turin and Cunéo over an area of some 600 hectares; it also occupies a few hectares in other parts of Italy. The crop is gathered and distilled during the first three weeks of August.

The essential oil of Italian-grown peppermint is superior to that of all others as regards mildness and perfume, but the supply is far too small to satisfy the home demand, let alone foreign markets. The author therefore urges that this plant should be more extensively grown in Italy.

Peppermint does very well as the first of a rotation of crops; it is not an exacting plant, and provided that the climate is sufficiently damp it can defy bad weather, and even storms, owing to the rapidity with which it produces new shoots and flowers. It flourishes in flat strong marly loams especially if rich in organic matter. One hectare yields from 175 to 200 quintals of fresh plants n normal years, and as much as 250 quintals in exceptionally favourable seasons.

In 1920, the plants fetched 30 *lire* per quintal, which meant a net profit of 100 % to the grower. From 120 000 quintals of green plants from Piedmont, from 25 000 to 27 000 kg., of essential oil was obtained (it takes about 4 quintals of plants to produce 1 kg., of essential oil). This was sold in 1920 at 250 *lire* per kg., which gave a large profit to the distillers.

The distillation of mint is carried out in the following manner: From 3 to 4 quintals of freshly-cut plants are placed in the still and pressed down well. Then the still is filled about two-thirds full with water, and the whole contents boiled for two hours, either over an open fire or else (which is better) by the direct or indirect steam. The only fuel used is wood. The essential oil that condenses in the worm of the still at the same time as the steam, subsequently flows into a Florence flask. The water, when separated from the essential oil, passes back into the still. In 24 hours, 10 to 11 distillations are effected with each still.

This industry which began in the most modest manner about fifty years ago, received a great impetus from H. CARLES, who introduced into Piedmont the cultivation of the English Mitcham peppermint which contains much more essential oil than the Italian variety.

59 - **The Prickly Pear in Australia.** — ALEXANDER, W. B. (Science Abstractor). *Institute of Science and Industry, Bulletin* No. 12, pp. 5-48. Melbourne, 1919 (1).

In Australia, the prickly pear is utilised for the following purposes: —

HUMAN NOURISHMENT. — The only species notified as being utilised for human nourishment in other countries are: *Opuntia Ficus-indica, O. decumana, O. streptacantha.*

LIVESTOCK FEED (2). — The pest pear (*O. inermis*) possesses a considerable value as a reserve feed in times of drought. But 4 trial feeding tests with cattle, milch cows, calves, and sheep have led to the following conclusions: —

(1) The forage should be well prepared before giving to the stock. It can be chopped up either by hand or by machine and fed in troughs,

---

(1) See *R.* Nov.-Dec. 1920, No. 1916.

(2) See *R.* March 1915, No. 299; Nov. 1915, No 1180; Feb 1917, No. 169. (*Ed.*)

or still better, roasted or heated in boiling water; this last method is the best.

(2) None of the above mentioned animals are much attracted to *O. inermis*; its chief utility consists therefore, in its employment as reserve forage in times of drought.

(3) A supplementary protein feed, such as flax cake, or maize forage, lucerne hay or soya is absolutely necessary.

(4) The addition of appreciable quantities of prickly pear to the daily rations for milch cows, lowers the percentage of fat in the milk and the quantity of butter produced, but increases to a certain extent the milk production. The milk is suitable for the manufacture of cheese. For milch cows, it is advisable to employ prickly pear as a part feed only.

5) *O. inermis* may be fed to breeding stock, provided that an additional quantity of protein feed is also given. The same thing applies to calves, in times of drought.

6) For ewes not giving milk, the ration should contain coarse straw; this feed is not suitable for breeding ewes and lambs.

7) Cattle fed on *O. inermis*, should be grazed on shrubby pasture land or where vegetation rich in protein content is avaitable.

8) During hot weather, the livestock fed on prickly pear is constantly in need of water.

GREEN MANURE. — That supplied by *Opuntia* enriches the soil in potash and organic matter (1). In Ceylon, India, South Africa, Mediterranean Coast, and occasionally in Australia, successful results have been obtained.

In 1913, CAMPBELL, analysed the by-products of *Opuntia* obtained by dry distillation, i. e. in a distillate. The percentage content was as follows:— Water 88.4; acids (determined as acetic acid) 0.154; ammonia, amines (primary and secondary (determined also as ammonia 0.005; tertiary amines (determined as pyridine); Residue, 4 % of crude tar and 4 % carbon.

In Australia the utilisation of the fruits of the prickly pear in the production of alcohol, and the fibres as first quality material for the manufacture of paper and cardboard, has not proved successful from the economic standpoint.

60 - **Cultivation of the Artichoke in the Roman Maremma, Italy.** — LAZI, A. in *La Nuova Agricoltura del Lazio*, Year VIII, No. 188, p. 123. Rome, Nov. 1, 1920.

VARIETIES AND CULTIVATED. — According to the author the best cultivated varieties are the Tuscan Violet or " nostrale ", the Empoli, artichoke, Venitian artichoke, and the large Roman artichoke.

CULTIVATION. — The artichoke needs a temperate climate, as frosts harms it very much, consequently, when digging over the ground in autumn or winter the plants should be earthed up well. The plant grows well in strong clay loams, and even better in open marly clay soils.

---

(1) See *R.* Nov. 1915, No. 1131. (*Ed.*)

The land is prepared at the beginning of autumn, when it is dug to a depth of 50 to 60 cm., after being well manured (about 800 quintals of manure per hectare). In October and November, after the land has been well prepared, the artichokes are planted 6 to 8 cm., deep. and 1 m., apart, leaving 1 m., between the rows. In the spring the soil is earthed up round the young plants with a wooden plough or hoe.

ANNUAL ATTENTIONS. — Land producing artichokes should receive a dressing of decayed manure in autumn, followed by digging in. The shoots which grow on the mother plant should be removed leaving only the strongest and best developed ones. Instead of good farmyard manure a fertiliser composed of 80 gm., mineral superphosphate + 20 gm. potassium sulphate + 20 gm., ammonium sulphate may be used per plant.

In March, hoeing and removal of the leaves is commenced. Four or five of the biggest leaves are taken from each plant and used as green fodder, but they must be given in moderate amounts to milking cows. The removal of the leaves continues until the beginning of May.

COST OF CULTIVATION. — At the present time, in certain parts of the Roman Maremma, a well-kept artichoke farm will bring in a yearly protfit of 11 000 lire for 10 or 12 years. A debit and credit account is summarised in the following Table (per hectare).

COST OF CULTIVATION.

	Lire
Digging at 50 cm., 250 days at 20 *lire*	5 000
Hoeing: 25 days at 15 *lire*	375
Manure: 80 cub. m. at 6 *lire* per cub. m.	320
Transport of manure: 10 *lire* per cub. m	800
Plantation: 7 days at 15 *lire*	105
Plants: 10 *lire* per thousand	100
Rent of land	270
Total	6 970
Interest at 5 % on capital	348

Expenses . . .	3 116
Net profit	**11 084**

PESTS. — The field mouse causes great damage by eating the collar of the plant, Zinc phosphide is a good preventive. During wet seasons, plant lice (*Aphis cardui*) attack the plant, but can be controlled by an ordinary soap solution. The leaves are attacked but not much harmed by the larvae of *Vanessa cardui*. Among the fungoid diseases mention should be made of *Peronospora gangliformis* Berk (= *Bremia Lactucae* Regel), which produces a kind of silvery mould on the under side of the leaves, attacking the calathides and causing rot. Spraying with a solution of borax or with milk of lime is effective.

61 - Chinese Tuberous Mustard *Sinapis juncea* var. *napiformis*. — DE NOTER, R., in *Le Jardin*, Year XXXIV, No. 743, pp. 157-158 + 1 fig. Paris, Oct. 20, 1920.

The author states that this exotic legume, which is eaten in winter is very hardy, for it withstood well the winter of 1917; it yields a first-class product.

The comestible part is the napiform root, which is about 15 cm., long and 5 to 6 cm., in diameter.

The soil should be well dug, light and have received abundance of fertilisers. The seed is sown in rows, 30 cm., apart, from the beginning of August, and watered frequently; when the plants have 3 or 4 leaves, they are thinned out to about 15 cm., apart.

They are gathered in 2 or 3 months. This mustard which is barely piquant in taste, will keep in a cellar or in a hog until April but can also be left in the ground and gathered when required.

62 - Apple Orchard Pruning Experiments in Vineland, Canada. — PALMER, R. F., in *The Agricultural Gazette of Canada,* Vol. 7, No. 9, pp. 754-755. Ottawa, Sept., 1920.

An experiment consisting of a comparative test of three different pruning treatments namely:— (*a*) Winter or dormant pruning; (*b*) summer pruning; (*c*) no pruning. About 15 different varieties were under observation.

Results showed that the heavy dormant pruned group made much less growth than either the unpruned or summer pruned trees and came much later into bearing and with a much smaller yields. It was evident that the lighter the pruning the greater was the growth the earlier the tree came into bearing, and the heavier the yield during at least the early period of the trees life. Unpruned trees made more growth than either of the other two systems, but in consideration of the increased cost of spraying, picking, growing lack of colour, and general undesirable condition of unchecked growth, light annual pruning is advised until the tree comes into bearing. After this, more severe pruning may be necessary to maintain a proper supply of new wood each year. This will of course vary with the variety.

63 - The Problem of Re-Afforestation in Spain. — *Real Sociedad Española de los Amigos del Arbol, Boletin Oficial de la Sociedad,* Year X, No. 102, pp. 1-5. Madrid, 1920.

General conclusions presented to the Spanish Government by the Eighth Section of the National Congress of Spanish Engineers. After enumerating the advantages that would accrue to the nation from re-afforestation, the report deals with timber production, forest management, the transport of forest products, mountain pastures, resin production, materials for the paper industry, cork, dry distillation of wood, the forest wealth of the Gulf of Guinea Colony, and river fisheries.

Timber production is now a matter of great economic importance, and as it is of special national interest, it is necessary to consider how the output can be improved, both as regards quantity and quality.

To increase the quantity, the management of the forests should be entrusted to the Public Services, and all schemes of management should be directed towards obtaining, within a short space of time, the best and highest yield, and of founding in forest regions, many trial Stations for native and exotic trees. In order to improve the condition of the stands, the forests, commencing with the most important, should be provided with easy and economic clearing tracks. The administrations should fix the price of trees sold to private individuals, according to the quality of the wood and the purpose for which it is to be employed. The physical and mechanical properties of the products should be studied experimentally, especially at the Central Technical Forestry Experiment Institute, which possesses all the means necessary for carrying out technical sylvicultural experiments. The formation of a State Forestry Reserve is also necessary for this purpose.

As regards the management of the forests, the Congress is of opinion that the regulations in force need immediate revision, and that an economic method must be substituted for the ordinary system of forestry ;

hitherto in existence. As regards transport, the report states that as making clearing tracks must be regarded as work of public utility, special legislation should be passed, inviting forest owners to contribute to the expenses of making the roads. It is equally important to give a strong impetus to the construction of secondary railroads, cart roads and district roads in the forest regions that are now at a great distance from the centres of consumption.

Further, given the great importance of the livestock industry, it is necessary to improve the pasturage on waste land, steppes, and other parts of Spain where the ground cannot be turned to better account. The forest zone must be divided into regions and sections, special study being devoted to the conditions of vegetation and the pastoral industry Experiment fields should therefore be made, the pastures improved, the seeds of suitable and selected forage crops produced and, in short, all this work should be co-ordinated, and publications issued dealing with these matters. In addition, the local Services should deal with questions of hygiene, the provision of drinking-troughs, and the construction of shelters for stock and shepherds.

With regard to the resin industry, the report states that the present system of collection should be altered, and that in the case of *Pinus Pinaster*, the Forestry Experiment Station should study some means by which both the wood and the resin of this tree could be used.

The conclusions of the Congress as to the paper industry are that is necessary to study the zones most suitable for the production of the raw material required; to create communication roads in the Pyrenean zone, where the pine and birch can be utilised, to intensify and extend the cultivation of esparto grass in the Mediterranean districts; to establish nurseries and distribute gratuitously rapidly-growing seeds and forest trees.

It is to the interest of the country that all the native cork should be worked up in Spain; therefore the tax of 5 *pesetas* per quintal on exports of sheet cork should be removed while, at the same time, the importation of all qualities of cork should be prohibited. The report also recommends the inception of experiments on the effect of potash upon cork production, both from the point of view of quantity and quality.

In order to assist the wood-distillation industry, the Congress proposes that the import duty on acetate of lime should be raised to 50 *pesetas* per quintal; that the entrance into Spain of methylated alcohol should be prevented by raising the import duty to at least 160 *pesetas* per hectolitre; and finally, that the railways should offer reduced tariffs for the transport of pyroligneous liquids, acetate of lime and especially for the charcoal produced by distillation. The competent Ministry is also requested to estimate quickly the approximate annual volume of the wood intended for distillation, and to include in the data all matters connected with this industry, such as the cost of wood and of labour, costs of transport, the most important markets for wood charcoal, etc. The report also states that it is necessary to draw up, without delay, schemes for the management of forests containing wood suitable for dry distillation, and able to furnish at least 1 000 to 1 500 metric tons of wood per annum.

The report also deals with the forest wealth of the Spanish Colony of the Gulf of Guinea, in so far as it recommends the nomination of a technical Commission for the study of the forests there, and the separation of the agricultural zone from the forest zone together with the creation of a Forest Service in the Colony for the purpose of directing forestry operations in such a manner that Spain may obtain the greatest advantage.

As regards the river fisheries of Spain, the report mainly deals with the conventions made with border States, and the means of promoting fresh-water fishing, which could produce an annual return of 79 million *pesetas*.

64 - **A Policy of Forestry for the Nation in the United States.** — GRAVES, H. S. (Forester, U S. Forest Service). — *United States Department of Agriculture, Circular 148, Office of the Secretary*, pp. 11. Washington, D. C., 1919.

A national policy of forestry seeks the protection and beneficial utilisation of the present forest resources, the renewal after cutting of forests on lands not needed for agriculture and settlement, the stability of forest industries and of satisfactory conditions for forest workers and the restoration of forest growth on lands now unproductive and idle.

The public interests in the continuance of forests justify and require direct public ownership of extensive areas, and also participation of the public in working out the problem of protection and renewal of private forests. A programme of forestry for the Nation should include action by the public through the United States Government and each State; action by landowners and operators, and the means of uniting the efforts of all for the achievement of a common purpose.

The States have not only the function of handling the public forests owned by them, but they have also a direct responsability in the protection and continuance of private forests. In this, the Federal Government should take part to meet interstate and national problems, to stimulate action by the States and to bring into harmony the efforts of the different States. A national policy must recognize also the problems of the private owners of forests. A programme in which the public participates and recognises industrial problems, such as taxation, would enable private proprietors to handle their forests in a way that would result not in a public injury but in making these forest serve in building up the localities in which they are situated.

PUBLIC FORESTS. — There should be an extensive programme of public forests, owned by the Nation, by the States, by municipalities, and too, by quasi-public institutions and organizations. The public forests in the United States to-day comprise about 25 per cent. of the total forest area of the country. They should be extended to include ultimately from 40 to 50 per cent.

PRIVATE FORESTS. — The safeguarding of private forests is possible through an organized system of protection, through the prohibition of destructive processes, and through the promotion of constructive measures of forestry. The participation, liberal cooperation and direction of the public in working out the problems involved are necessary for success. Besides protection against fire insects and disease, the renewal of forests on lands not needed for agriculture is an essential feature of a national policy of forestry. The first steps in this undertaking are to determine in each region:

1. The circumstances under which fire protection alone will not suffice to prevent wastage of the land under prevailing methods of lumbering;
2. The additional measures necessary to secure conditions favorable for natural renewal;
3. The classes of land upon which forest growth should be continued;
4. The co operation that should be given by the public to make feasible in practice the measures that may be necessary for the owners to take;
5. The legislation needed to bring these measures into practice, as a part of the State's programme of forestry.

Every encouragement should be afforded to bring about close utilisation of timber in the forest and to prevent losses in the handling and use of the manufactured product. This will be acomplished largely through co-operation and research. in bringing information to the knowledge of operators and users of wood products. It is a problem of investigation and industrial education, in which the public should take the leadership.

ASSISTANCE AND CO-OPERATION ON THE PUBLIC. — In a national policy of forestry the public itself should assume certain responsibilities and certain burdens. It should co-operate with and assist private owners in carrying out their part of the undertaking The measures of co-operation fall under the following heads:

1. *Fire protection.* — The public should directly share the burden of fire protection, especially in a preventive system and in the cost of suppression.

2. *Assistance in forestry* — The public should assist owners in working out plans for cutting that will promote natural reproduction, in planting, and in other measures of forestry. The State should offer planting stock at cost and co-operate with the owners in establishing plantations.

3. *Forest loans.* — It has been suggested that existing legislation concerning farm loans should be extended to include loans for the purchase and improvement of forest lands, to encourage the holding of lands previously acquired, where the purpose of the owner is to hold and protect cut-over lands or those having growing timber, to reforest lands by seeding or planting, or to use other measures in promoting forest production. To obtain the benefit of such loans, which should be for a maximum period of 50 years, the land owner should enter into a specific obligation to retain the land in growing timber and protect and care for it during the duration of the loan.

5. *A survey of forest resources.* — Funds should be provided whereby the Federal Government in co-operation with States and private interests may make a survey of the forest resources of the country.

6. *Land classification.* — The public should co-operate in land classification to aid owners to put their lands to the most productive use.

7. *Research work.* — Adequate funds should be provided to enable the Government and other public agencies to carry on investigation work needed in carrying out a national policy

of forestry. This would included investigations on a large scale for determining the best methods of forest practice, and also research in forest products.

8. *Forest insurance.* — As soon as forest property becomes secure under systematic protection, fire insurance comes within the range of feasibility. Every encouragement should be given to plans of insurance such as that already inaugurated in the north-east.

A programme for the nation must be an aggregate of local programmes adapted to différent conditions, and correlated and standardised through the U. S. Federal Government to meet the broader requirements of the whole country. A national programme can not put into effect in its entirety at once. Local programmes will also probably have to be worked out by steps. Some States are already able to go forward more rapidly than others, partly because of ther financial strength and partly because experience has already demonstrated the methods of protection and forestry required to secure results on this ground.

The initiation of a national policy of forestry requires as one of the first steps the passage of a federal law that recognizes its objectives and provides the Government with authority and means to extend co-operation with the States in protecting and perpetuating the forests under their jurisdiction along the lines of the foregoing statement. At the same time federal appropriations for the purchase of forest lands should be greatly increased.

65 - **New Trees Obtained by Hybridisation, Fast Growing Kinds and Hence Early Supply of Timber.** — See, No. 40 of this *Review*.

66 - **The Cork Industry of Spain in 1919.** — BORRALLO, J. A., in the *España Forestal*, Year VI, No 58, pp. 107-109 Madrid, July, 1920.

In 1919, the yield of cork was 80 million kg., valued at 9.20 *pesetas* per kg., but in 1916 it was 70 million kg. and sold at 9.36 *pesetas* per kg. The total value realised in 1919 was 15 899 966 *pesetas*, an increase of 1 656 549 *pesetas* over 1916. The chief centres of production were the provinces of Cadiz, Huelva Badajoz, Caceres, Malaga, Seville, and Cordova.

The cork industry, which suffered very much during the war,largely because the best workers emigrated to America, had recovered by the end of 1919 owing to the increase in foreign orders

The following Table gives the Spanish imports and exports of cork in 1919 in kg. :—

Imports.

	Kg.
Algeria	399 098
France	209 116
Morocco	27 232
Portugal	1 084 706

Total . . 1 720 152 valued at 461 442 *pesetas*, plus 13 216 kg., of manufactured cork valued at 28 677 *pesetas*.

Exportation.

Country	Raw cork kg.	Cork in pieces kg.	Stoppers kg.	Other forms kg.	Parings kg
Austria-Hungary	—	—	27 803	—	—

The grand total is 46,453,459 kg., valued at 37 952 172 *pesetas*.

LIVESTOCK AND BREEDING

67 – **Principal Poisonous Plants in Canada.** — Flyes, M.lle F. (Assistant Botanist) in *Dominion of Canada, Department of Agriculture, Dominion Experiment Farms, Bulletin* No. 39, pp 1-112. + 40 pl. Ottawa 1920.

This Bulletin, in addition to the numerous illustrations given by the author, describes in detail the various species, and it is compiled with the intention of presenting the farmer and plant breeder with a means of identifying the poisonous plants which are to be found in the meadows and pastures. The symptoms evinced by poisoning from these plants are described, and the methods of treatment indicated. A bibliography of 24 works und a list of species is included in the appendix.

The species examined were as follows:

Hypocreaceae: — Rye "ergot". (*Sclerotium Clavus* Fries = *Claviceps purpurea* Tul.

Polypodiaceae: Bracken (*Pteris aquilina* L. = *Pteridium aquilinum* (L) Kuhn).

Equisetaceae: Common or Field Horse-Tail (*Equisetum arvense* L.).

Gramineae: "Darnel" (*Lolium temulentum*) — Cause of splitting: — Awns and seed of Porcupine Grass (*Stipa spartea* Trin.) and of Needle grass (*S. comata* Trin. and Aupr.) — Sanbur thorns (*Cenchrus tribuloides* L.) — Silk fibres of *Setaria* spp. — Seeds of Squirrel tail grass or wild barley (*Hordeum jubatum* L.) — Wild oats (*Avena fatua* L).

ARACEAE: Jack in the pulpit (*Arum triphyllum* (L.) Torr.) — Green dragon (*Arisaema Dracontium* (L.) Schott) — Arrow arum (*Peltrandra virginica* (L.) Kunth) — Water arum (*Calla palustris*) — Skunk cabbage (*Symplocarpus foetidus* (L.) Nutt) = *Spathyema foetida* (L.) Raff.) — Western skunk cabbage (*Lysichiton camtschatcense*. Schott).

LILIACEAE: Zygadenus or death camas (*Zygadenus venenosus* Rydb.) = *Toxicoscordium gramineum* Rydb.) — Smooth camas (*Zygadenus chloranthus* Rich. = *Anticlea elegans* (Pursh) Rybd.) — False hellebore (*Veratrum viride* Ait).

IRIDACEAE: " Blue flag " (*Iris versicolor* L.).

URTICACEAE: "Slender nettle» (*Urtica graciles* Act.) and other stinging nettles.

PHYTOLACCACEAE: " Poison poke " (*Phytolacca decandra* L.; *P. Americana* L.). .

CARYOPHYLLACEAE. — Purple cockle (*Agrostemma Githago* L); Soapwort (*Saponaria officinalis* L.); Cow cockle or cowherb (*Saponaria Vaccaria* L. = *Vaccaria Vaccaria* Britton).

RANUNCULACEAE. — Cursed crowfoot (*Ranunculus scleratus* L.); Tall buttercup (*R. acris* L.); *R. abortivus* (*R. reptans* L.); Pasque flower (*Anemone patens* L. var. *Wolfgangiana* (Bess) Kock = *Pulsatilla patens* (L.) Mill.); marsh marigold (*Caltha palustris* L.) The species suspected are :— Yellow marsh marigold (*C. asarifolia* D. C.); Mountain marsh marigold (*C. leptosepala* D. C.); Dwarf marsh marigold (*C. Chelidonii* Greene), Larkspurs (*Delphinium* spp.); White baneberry (*Actaea alba* (L.) Mill.); Red baneberry (*A. rubra* [Ait] Willd.); Western red baneberry (*A. arguta* Nutt.).

MENISPERMACEAE: Canada moonseed (*Menispermum canadense* L.).

BERBERIDACEAE: " Blue cohosh " (*Caulophyllum thalictroides* (L.) Mich); May apple (*Podophyllum peltatum* L.).

PAPAVERACEAE: " Bloodroot (*Sanguinaria canadensis* L.); Celandine (*Chelidonium majus* L.).

LEGUMINOSAE: Lupins (*Lupinus* spp.); Locoweed (*Oxytropis Lamberti* Pursh).

EUPHORBIACEAE: " Sun spurge " (*Euphorbia helioscopia* L. = *Tithymalus helioscopia* (L.) Hill); Cypress spurge (*Euphorbia cyparissias* L. = *Tithymalus cyparissias* (L.) Hill).

ANACARDIACEAE: Poison ivy (*Rhus Toxicodendron* L. = *Toxicodendron Toxicodendron* (L.) Brit); Poison sumac (*Rhus Vernix* L. = *Toxicodendron Vernix* (L.) Kuntze.

THYMELEACEAE; Wicopy. (*Dirca palustris* L.) Mezereon (*Daphne Mezereum* L.).

UMBELLIFERAE; Poison hemlock (*Conium maculatum*); Water hemlock (*Cicuta maculata* L.); Bulbous water hemlock (*C bulbifera L.*); Water parsnip (*Sium cicutaefolium* Schrank).

Ericaceae "Mountain laurel" (*Kalmia latifolia* L.) Sheep laurel (*Kalmia angustifolia* L.).

Apocynaceae; Spreading dogbane (*Apocynum androsaemifolium* L.); Black Indian hemp (*A. cannabinum* L.).

Asclepiadaceae "Butterfly weed" (*Asclepius tuberosa* L.); Swamp milkweed (*A incarnata* L.); Common milkweed (*A. syriaca* L.); Showy milkweed (*A. speciosa*); Oval leafed milkweed (*A. ovalifolia*).

Solanaceae "Bittersweet" (*Solanum Dulcamara* L.); Three flowered nightshade (*S. Triflorum* Nutt.); Common nightshade; (*S. nigrum*) L.); Black henbane (*Hyosycamus niger* L.); Thorn apple (*Datura Stramonium* L.); Purple thorn apple (*Datura Tatula* L.) *D. Metel* L.).

Lobeliaceae "Indian tobacco (*Lobelia inflata* L.); Great lobelia (*L. syphilitica* L.); Cardinal flower (*L. cardinalis* L.).

Compositae "While snakeroot" (*Eupatorium ageratoides* L. = *E. urticaefolium* Reich.; Sneezewort (*Helenium autumnale* L.); Ragwort (*Senecio Jacobaea* L.).

68 - **The "Whorled Milkweed„ (*Asclepias galioides*), a Plant Poisonous to Livestock.** — Marsh, C. D., in *U S. Department of Agriculture, Department Circular* 101, pp. 2, 1 fig. Washington, D. C., May, 1920.

The whorled milkweed grows abundantly in some sections of southwestern Colorado, southern Utah, and the northern counties of Arizona and New Mexico. It is from 1 to 3 feet in height and is not found above an altitude of 7500 feet. It is one of the most poisonous of the plants injuring livestock. As small a quantity as 2 ½ oz of the green plant may kill a sheep, and 2 ½ lb., may kill a 2-year-old steer. Horses are not likely to eat it, but if they do they are as easily poisoned as sheep. Many animals have been killed by eating hay containing the dry plant. No remedy has been found. The plant is exceedingly difficult to eradicate, but, by cutting it down before the seeds are formed, much can be accomplished in pastures and along trails.

69 - **Studies on Dourine** (1). — Formad, R. J. (Pathological Division, Bureau of Animal Industry, U. S. Department of Agriculture), in the *Journal of Agricultural Research*, Vol. XVIII, No. 3, pp. 145-154. Washington, November, 1, 1919. — II. Sergent, E., Donatien, A. and L'Héritier, A. (Pasteur Institute of Algeria), Des étalons guéris cliniquement de dourine peuvent rester des porteurs sains de germes pathogènes, in the *Bulletin de la Société de Pathologie exotiques*, Vol. XIII, No. 7, pp. 515-518. Paris, July 7, 1920. — III Sergent, E., Donatien A. and L'Héritier, A., Du diagnostic expérimental de la dourine, *Ibid.*, pp. 518-520. — IV. Clerici, A., Malattie infettive dei cavalli, nuovi metodi di cura, in the *Industrie Italiane Illustrate* (I. I. I) Section D. Agricoltura, Alimentazione e Industrie agrarie, No. 10, p. 14. Milan, October, 1920.

I. — The most essential factor in the suppression of dourine is a correct diagnosis. For this reason, the Bureau of Animal Industry of the U. S. Department of Agriculture has devoted much attention these last 5 years, to perfecting the technique of the complement fixation test as applied to this disease.

---

(1) See *R.* Jan. 1916, No. 72. (*Ed.*)

In the literature dealing with dourine, the clinical phase (etiology, symptoms, treatment) have received far more attention than the pathological phase, namely, the alterations this disease produces in the tissues of the animal. As little has been done in the United States to determine whether the microscopic changes described by European investigators are identical with those observed in horses in north America that are attacked by dourine, the author has undertaken the study of this question, and has obtained the results given below.

Microscopic examination of the brain reveals no appreciable changes in the nerve cells, supporting tissue, or blood vessels; the existence of lesions cannot be demonstrated, even by aid of the most delicate staining methods, in any part of the cervical, anterior, or dorsal portions of the spinal method. In the posterior dorsal part, the lesions were very slight but gradually increased in severity in the lumbar region becoming very accentuated in the region of the sacrum.

In all the phases of the disease degeneration of the sensory ganglia was present, to an extent that varied from the initial chromatolysis stage, which was scarcely revealed by NISSEL's method, to the advanced degeneration and disintegration present at the plasmolysis stage. The cells of the motor ganglia and those of CLARK's column showed such slight alterations that it was difficult to observe chromatolysis The nerve celles of the spinal ganglia showed different degrees of chromatolysis. The most noticeable changes were those taking place in the sensory nerves of the sacral region where the disintegration of the chromatophyll granules was followed by atrophy and sclerosis, and invariably accompanied by a peripheral displacement of the nuclei This was not observed in the nerve celle of the spinal chord.

The degeneration of the myelin in the medullary fibres was as accentuated as the degeneration of the nerve-cells. The black glomerulae of degenerated myelin stained with osmic acid, according to MARCHI's method, were characteristic of the endoneural and extraneural fibres of the grey matter of the dorsal processes and the roots of the dorsal nerve, as well as of the *funiculus cuneatus* (BURDACH's column) and the *funiculus gracilis* (GOLL's column) in the white matter of the spinal marrow. The changes were confined to the lumbar and sacral regions; the degeneration was still more marked in the sciatic nerve. It may therefore be concluded that the origin of the disturbance is rather peripheral than central.

II. — In 3 stallions that were clinically cured of the disease, perfectly fit for service, and with blood which was no longer infectious, even if several litres were examined, the authors observed the sudden re-appearance of the trypanosomes in the peripheral blood, after 14 months, 2 years, and 3 months, respectively.

A stallion effected by dourine may thus remain a source of infection, even when to all appearance it is perfectly cured. Hence, all stallions that have had dourine should be excluded from the stud, and ought to be killed or castrated, according to their condition.

III. — 1) The pathogenetic agent of dourine (*Trypanosoma equiperdum*) occurs sometimes in such small numbers in the general circulatory system of horses with all the symptoms of a severe attack of the disease, *i. e.*, the typical " plagues ", etc., that the inoculation of animals susceptible to the malady, even if $^{1}/_{50}$ or $^{1}/_{60}$ of the whole total blood-volume of the horse is injected at the same time, has, no effect.

(2) Thus, only positive results of inoculation are of any use in the diagnosis of dourine or in estimating the results of treatment.

IV. — Dourine is one of the most interesting of the infection diseases of the horse to which veterinary science has of recent years been obliged to devote special attention. Though for nearly 80 years it had not been seen in Italy, dourine reappeared in 1919, and owing to the difficulty inexpert veterinaries find in diagnosing the disease, it became very widespread in North and Central Italy and in Sicily When it was first reported from Crema, during the covering season, Prof. STAZZI had discovered 60 cases among the stallions and over 1 000 among the brood-mares. As soon as the epidemic was recognised and rigorous measures adopted for stamping it out, the disease became of much less frequent occurrence, and during the covering season of 1920, at Crema itself, Prof. STAZZI only reported a single case among the stallions and 9 cases among the mares.

Dourine has long been known in Europe, owing to its frequent appearance during the last few centuries in France and the Western States of Germany, where it was introduced by Arab stallions from Africa. The name, it bears was given to it by the Arabs. It has, however, been stated that the disease, which has recently broken out in Italy, is not absolutely identical with the African dourine, but is another form of the malady which is wide-spread in Russia, Hungary, Croatia, East Prussia, Rumania, and Bulgaria. In order to distinguish it from the other type, it can be called the " malignant coition disease " of East and North Europe

This identification rests upon the identity of the pathogenetic agent, on the symptoms, especially upon the course of the malady, and finally upon the epidermiological symptoms, for it has been observed that this time also, as in the case of the outbreak of 1838-1840, the disease entered Italy across the Eastern frontiers The same form has also been predominant since 1886 in North America (United States and Canada).

This malignant coition disease is very contagious, and is transmitted, as its name implies, at the time of service. For this reason, as well as on account of the resemblance of some its symptoms to those of syphilis, it still goes by the name of " horse syphilis ". The pathogenetic agent is *Trypanosoma equiperdum.*

The symptoms of the disease are very variable, and its course often shows great differences from one case to another, although as a rule it is less rapid and fatal than the similar disease which originated in Africa. Thus in outbreaks of the E. European form, the mortality is never so high (80 $^{0}/_{0}$) and much more success has been obtained with prophylactic and systematic treatment than in the case of the African type.

During the course of the disease, 3 phases are generally to be distinguished.

1st *phase*; *initial symptoms.* — These usually take the form of a swelling of th external genitalia, accompanied by ulceration. There are never many ulcers, and often only one. In many cases, these symptoms are not very noticeable, hence the first phases of the disease frequently escape observation.

2nd *phase, or that of the plagues.* — At this stage, the trypanosomes have already penetrated into the blood; if some of them remain in the smalle t vessels in the skin, inflammation sets up and shows itself in the formation of plagues of the most varied form: rings, half-circles, bands, pads. These plagues constitute one of the most typical symptoms of the disease.

3rd *phase or that of nervous troubles.* — These disturbances are caused when the trypanosomes are located in the trunks of the nerves and in special regions of the nervous system. They differ according to whether the nerve alone or the nerve centre is attacked; thus disturbances are observed such as itching, sharp pains in the back legs, as well as malnutrition of the tissues (herpetic eruptions, occurring along the croup or the intercostal spaces); intermittent swelling of the abdomen or flanks; difficulties of movement.

Among the last-mentioned troubles, some are so characteristic as at once to reveal the nature of the malady. Thus, when the nerve trunks which innervate the limb muscles are attacked, the lower segment of the limb tends to fall; hence, the animal, to avoid stumbling at every step; raises this part of the leg much higher than normally, so that it seems to slide first on one leg and then on the other. When, however, the nerve trunk supplying branches to some of the respiratory organs is affected, rapid paralysis of respiration may ensue, and then the animal, after drawing several irregular, rattling breaths, dies almost instantaneously.

As regards treatment, owing to the manner by which contagion is effected, control mesasures are easily applied. Strictly speaking, all that is necessary is the scrupulous observance of the rules of hygiene and of cleanliness already laid down by veterinary science for the purpose of combating the infectious diseases of animals. In other words, no animal whether male or female must be used for reproductive purposes, if it is suffering from this malady. By rigorously carrying out this system, Prof. STAZZI has succeeded in reducing the propagation of the disease to a minimum in the district of Crema, where last year it had already assumed disquieting proportions. French veterinarians accustomed to control dourine which, as has already been said, is more malignant than the coition disease now present in Italy, also employ individual prophylactic measures at the moment of service in districts where the malady has been reported, and rub an antiseptic ointment upon the external genitalia of the brood-mares. This, however, entails some loss of time and considerable expense, and it has been found in Italy that the same end can be attained by simple supervision.

When the disease has already broken out, good results have been obtained in many cases by the use of arsenical compounds, such as atoxyl and salvarsan, which have been employed against several other disease due to trypanosomes. The latter, which is made in Germany can be substituted by an Italian product, jacol, which leaves nothing to be desired, either as a regards its mode of application or its effect.

70 - **Aphthous Fever in Indo-China** (1). — I. SEILLIER, E. A. (Directeur des Etablissements Messrs Lapicque et Cie., Laos), La fièvre aphteuse au Laos, in the *Bulletin Scientifique de l'Institut de Saigon*, Year II, No. 9, pp. 260-262. Saigon, September, 1920. — II. LE LOUET, G. M. (Directeur du Service Vétérinaire, Zootechnique et des Epizooties de Cochinchine), La fièvre aphteuse, considérations techniques. *Ibidem*, pp. 257-160.

I. — At the beginning of March, 1920, aphthous fever appeared in Laos (and in Siam) among the work-oxen. Few of these died, and the disease nearly always attacked over-tried animals, the breeding herds of the peasants remaining almost immune. The buffaloes were the first to contract the fever.

The natives have no empiric remedy for the disease, as it seldom occurs in Laos, its last appearance there dating back to 1899 or 1900. The symptoms were little defined, and many animals recovered without their owners troubling about the matter or separating them at night from the healthy individuals. Naturally, the disease soon spread to the breeding herds, and then the author was able to follow its course fairly accurately. He gives some data as to the course of the disease and advice regarding the treatment of infected animals and the precautions to be taken to prevent the spread of the fever.

II. — On reading the preceding article the author was induced to collect some technical data referring to aphthic fever in general.

This question is of paramount importance to Indo-China, as the disease is now rife in Annam, Cambodia, Cochin-China, Laos, and Siam, and perhaps in other regions that have relations with the Indo-Chinese Peninsula.

According to the author, the spread and virulence of the disease in Indo-China are restrained by the combined action of the light, the solar heat, and the extreme dryness of the air, which is a very strong action in this tropical country and quickly renders innocuous the aphthic virus, as, in spite of its subtlety and easy diffusibility, it is quickly destroyed.

The author mentions useful data regarding the disease, questions of immunisation, relapse, aphthisation, etc.

71 - **Inoculating Cattle against Tuberculosis.** — CALMETTE, A. and GUÉRIN, C., in the *Annales de l'Institut Pasteur*, Vol. XXXIV, No. 9, pp. 553-560 1 fig. Paris, September 1920.

The experiments carried out by the authors from 1912-1915 revealed the following facts:—

(1) By means of successive series of cultures of the bacillus of bovine tuberculosis, a race of non-tuberculigenous bacilli can be obtained

---

(1) See *R.* Sept., 1920, No. 882. (*Ed.*)

that are perfectly tolerated by cattle and other animals susceptible to the virus of tuberculosis.

(2) This non-virulent race behaves as a true vaccine, in that, when injected in the right amount into the veins of cattle, it makes these animals immune, not only against experimental test inoculation, but also against infection due to living in close quarters in a contaminated shed.

(3) This immunity, which presumably depends upon the presence of the non-virulent bacilli in the organism, only lasts 18 months after vaccination, but it can be conferred again by annual vaccination, a process which in itself is quite harmless.

72 - **Species of Cattle Piroplasma and Their Carriers.** — BRUMPT, E. (Laboratoire de Parasitologie de la Faculté de Médicine de Paris), in the *Bulletin de la Société de Pathologie exotique,* Vol. XIII, No. 6, pp. 416-460. Paris, June 9, 1920.

The author gives a detailed account of the micro-organisms producing cattle piroplasmosis, namely 7 species of *Piroplasma* and 2 species of *Anaplasma,* and he describes the morphological and biological characters that distinguish them.

The species studied are: —

Piroplasma bovis, transmitted by *Ixodes ricinus* (*Haemaphysalis punctata*), is probably an accidental parasite of this species.

P. argentinum, transmitted by *Margaropus australis. P. bigeminum* transmitted by *M. annulatus* and kindred forms: *M. australis* in Australia, *M. decoloratus* in S. Africa, and *M. calcaratus* in N. Africa; it has also been transmitted experimentally by *Rhipicephalus appendiculatus* and *Haemaphysalis punctata.*

Theileria parva is usually transmitted by *Rhipicephalus appendiculatus* (= *R. nitens*) which changes its host 3 times. *R. evertsi, R. capensis,* and *R. simus* can also transmit this organism. Some writers consider *Hyalomma aegyptium* also as a carrier. In Macedonia, Trans-Caucasia, and Tunisia, *Rhipicephalus bursa* and *R. sanguineus* are also probably carriers of *Theileria parva.*

Theileria mutans is transmitted by *Rhipicephalus simus, R. evertis* and, occasionally, by *R. appendiculatus.* It also be spread by *Hyalomma aegyptium,* while *Rhipicephalus bursa* and *R. sanguineus* are other suspected and probable hosts.

Anaplasma marginale can be transmitted by *Margaropus decoloratus* and by *Rhipicephalus simus. Anaplasma centrale* is transmitted by *Margaropus decoloratus.* The carrier of *Anaplasma argentinum,* which is morphologically identical with *A. marginale,* and is believed to have been introduced into South America by cattle imported from Spain, has not yet been determined, but is probably a species of *Amblyomma.*

It has hitherto not been possible to decide the pathogenic function of *Piroplasma hudsonius bovis* in British Columbia, but it is probably transmitted by *Dermacentor venustus.*

The cattle of Algeria and Tunis are often attacked by different diseases having in common the symptoms of more or less pronounced jaundice, serious anaemia, and often high fever, sometimes of a hemoglobinuric type. These affections are all known by the Arabs under the names of " Soufir ", Bon-Soufir " or " Soufir-ghrabi ", and are called jaundice by the colonists. It is probable that these forms of jaundice are the same as the " gall-sickness " of South Africa. These diseases are some of the most serious hindrances to stock-rearing in North Africa. In Algeria and Tunisia, they are found chiefly on low, damp ground, and seem to occur but rarely on the high plateaux.

According to the author, the name jaundice is given to different diseases, and in particular to:

(1) A form of piroplasmosis due to *Piroplasma bigeminum*, transmitted by *Margaropus calcaratus*.

(2) Affections produced by *Theileria mutans*.

(3) A form of anaplasmosis produced by *Anaplasma marginale*.

(4) A disease of which the etiology is so far unknown, but which goes by the name of bilious hemoglobinuric cattle fever.

73 - **The Origin of Lactose and Lactosuria in Cows** (1). — CAMPUS, A. (College of Veterinary Medicine at Turin), in the *Nuovo Ercolani*, Year XXV, No. 12, pp. 151-157. Turin, June 30, 1920; Nos. 13-14, pp. 161-170 + bibliography of 48 publications. July 15-31, 1920.

After having set forth all the different theories as to the origin of lactose, the author suggests 2 possibilities:— (1) That one molecule of glucose is transformed into galactose, and that by the subsequent union of this with a glucose molecule, lactose is formed; (2) that lactose is the result of the union of two glucose molecules, with the formation of a disaccharide, which is afterwards changed into lactose by means of a stereochemical modification.

Seeing how few experiments have so far been made in this connection, it is impossible to say which hypothesis is correct. It is certain, however, that lactose is derived from the glucose contained in the blood, and that glucose is transformed into lactose in the mammary gland.

Studies of lactosuria in animals are few in number, there being only those of LEBLANC and PORCHER.

In the urine of pregnant domestic animals, the presence of lactose has often been observed some days before delivery. The author has found it 16 days before calving, in the case of one cow, and 14, 9, or only 2 or 3 days before in that of others. Although the elimination of lactose usually continues, it is frequently intermittent. In a well-fed Piedmontese cow, producing 15 litres of milk a day, lactose appeared in the urine on the 16th day previous to calving, disappearing on the 15th, and reappearing on the 10th day, only to disappear once more, and to return 3 days before calving.

As regards the amount of lactose eliminated during the period preceding delivery, this has been found to vary in different animals. According to **Porcher**, it seems that, in some cows, the lactose increases every day, attaining its maximum on the day of calving. Other observers maintain that the amount varies every day and sometimes very considerably.

---

(1) See *R.*, Jan., 1919, No. 79. (*Ed*)

The results obtained from the examination of the urine of a Valdostana cow, 7 years old, which in the full lactation period yielded 20 litres of milk a day, are as follows:—

8 days before calving	traces of lactose were	found in 100 cc. of urine
7 » »	» » » 0.830 gm.	» » » » »
6 » »	» » » 0.955 »	» » » » »
5 » »	» » » 0.670 »	» » » » »
4 » »	» » » 0.475 »	» » » » »
3 » »	» » » 0.545 »	» » » » »
2 » »	» » » 0.504 »	» » » » »
1 » »	» » » 0.545 »	» » » » »
the day of calving	» » » 0.950 »	» » » » »

It should be noted that the amont of lactose eliminated every day shows slight oscillations.

During the period subsequent to calving, the lactosuria lasts only a short time. **Leblanc** and **Porcher** found it until the 6th day, and it seems to be connected with the amount of lactose eliminated before calving.

The lactose content of the urine also varies during 24 hours; thus, in the case of the same cow, in the morning, there were 0.445 gm. in 100 cc of urine, whereas in the afternoon, there were only 0.300 gm. These experiments confirm the truth of another statement, namely, that if milking or suckling is suspended, the lactose either reappears, or the amount evacuated the preceding day is increased. This led the author to conclude that the amount of lactose eliminated in the urine is in direct proportion to the quantity of milk yielded by the cow.

As regards any relation between the amount of lactose present in the urine before calving, and the subsequent milk production, as demonstrated by the two following Tables, giving the amount of lactose in 100 cub. m., of urine from two cows of the same breed and yielding respectively 14 and 20 litres of milk a day during the period of the greatest milk production, the author does not consider himself justified in drawing any practical conclusions.

Cow yielding 14 litres of milk.

74 - **Inoculation with Serum, as a Prophylactic against Swine Fever.** (1) — GARCIA IZCARA, D, (General Inspector of Hygiene and Veterinary Sanitation), in the *Boletin de Agricultura tecnica y económica*. Year XII, No 138, pp 418-420 Madrid, June 30, 1920

Experiments carried out with a view to determining whether inoculation with serum renders animals immune to swine-fever.

An attempt was made to obtain a more active serum by substituting intraperitoneal injection for subcutaneous injection, and by replacing Iberian pigs, which are excessively susceptible, by Celtic swine, which are very resistant to the action of the virus.

First, 69 pigs were injected with 20 cc ; 10 days later, the animals were injected with ¼ cc, of virus, a third similar injection being made after 10 days. Eight days subsequent to this last injection, the 69 pigs were removed to infected places and divided into 5 lots, the first containing 10 animals, the second 20, the third 6, the fourth 8 and the fifth 25 Lots 2, 3 and 5 were inoculated with the serum in July, 1919, when 3 months old, and until they reached the age of one year, showed no abnormal symptoms Lot 4 was inoculated when the animals were 8 months old, and till they attained 17 months, they manifested no sign of disease. All the pigs had received an injection of 20 cc., of serum, 0 25 cc., of virus being injected the first time and another 0.25 cc. the second time.

Sucking-pigs were also inoculated with serum to see how far they could be rendered immune. Experiments were made upon 1309 of these animals divided into 5 lots, containing respectively 100, 200, 207, 213 and 319 head. All were treated with 20 cc. of serum and received 2 injections of virus, the first of 0.25 cc., and the second of 0.5 cc.

At the time of inoculation with serum, Lot 1 was composed of pigs 40 days old. Nine of them (9 %) died as a result of the treatment, whereas the deaths among the 50 control animals were only 30 %. Lots 3, 4 and 5, which were made up of pigs 15 days old, showed no abnormal symptoms after 3 or even 4 months.

In conclusion, inoculation with serum is to be recommended for large animals when the fever has made its appearance, for the immunity gained is passive and of short duration.

Inoculation with the serum is the method of immunisation that has given the best results in the experiments carried out by the Stock-Breeding Association.

75 - Skimmed Milk as a Supplement to Maize in Feeding.— OSBORNE, T B , LAFAYETTE, B , and WAKEMAN A J , in *The Journal of Biological Chemistry*, Vol. XLIV, No. 1, pp. 1-4, Figs 1. Baltimore, M. D , October, 1920.

Good results had previously been obtained with the mixture of maize meal and skimmed milk in the promotion of rapid growth of young animals as well as poultry. The high cost of these food products and the necessity of their use in the most efficient proportions led to the experiments described in this paper:--

I. — Four albino rats were fed on a mixture of 91.5 % yellow maize meal and 8.5 % of " Krystalak " a preparation of dried skimmed milk containing 35 % protein and 2 % fat. The authors support the statement made by the former investigators HART and STEENBOCK, that a highly efficient protein mixture is not obtained until the proportion of liquid milk to maize meal reaches 1:1 ; in this proportion the milk nitrogen constitutes approximately 30 % of the total nitrogen of the ration. According to other information 88 % yellow maize meal supplies enough of the fat soluble vitamine for normal growth and reproduction of albino rats when a salt mixture containing sodium chloride, calcium lactate and ferric citrate is also added, and the maize proteins supplemented with casein. The authors therefore consider their own mixture to be adequate in respect to this food accessory, but it was found that the salts supplied by the milk were not sufficient to supplement adequately the recognised mineral deficiencies in maize, and it was necessary to add a standard salt mixture before normal growth was made (2). Results indicated that the mixture of yellow maize meal, skimmed milk solids and salts may be slightly deficient in fat soluble protein. The deficiency in mineral matter may however be compensated for by the addition of green fodder to the diet or by the addition of about 1 lb., each of calcium carbonate and sodium chloride per 100 lb., of maize meal.

76 - The Mechanical Power Required for Crushing Oil-Cakes as a Factor in their Selection. — RINGELMANN, in *Comptes rendus de l'Académie d'Agriculture de France*, Vol. VI, No. 28, pp. 704-707. Paris, October 6, 1920.

In valuing feeding cakes, their food value represented by the protein content, is the chief factor taken into account. As, however, it is most profitable for the agriculturalist to purchase his cakes whole, the cost of crushing must also be considered, and this varies in the ration of 1:5, according to the hardness of the cakes.

The accompanying Table summarises the results of the experiments carried out with a good type of hand cake-crusher, with a single pair of cylinders, 10 kg., of each cake being used,

According to these experiments, the author thinks the following classification may be made:—

---

(1) See *R*, June, 1920, No. 616.

(2) See *R*, October, 1919, No 1175. (*Ed*)

Cake	Country of origin	Density	Protein	Mechanical power used in crushing 1 kg. of cake
			Per cent.	Kg.-metres
Local colza	France	1.20	34.68	85.3
Cotton (1st production)	Egypt	1.19	25.00	88.2
Local flax	France	1.23	31.18	91.9
Sesame	?	1.13	41.67	94.2
Red copra	Singapore	0.93	24.50	96.5
Coconut	Ceylon	0.91	20.55	119.2
Decorticated peanut	Bombay	1.28	47.71	138.9
Cotton (2nd production)	Egypt	1.31	25.00	158.2
Niger	Africa	1.27	38.75	344 8
White poppy	Smyrna	1.21	37.75	419.1

Soft cakes: — local colza, Egyptian cotton (1st production), local flax, sesame, red copra, and coconut.

Hard-cakes: — decorticated groundnut and Egyptian cotton (2nd production).

Very hard cakes: — Niger and white poppy.

This classification as regards the cakes tested, may undoubtedly vary according to the oil-factories.

In short, the protein content is not a sufficient guide to the selection of a cake and the cost of crushing it must also be taken into consideration, that is to say, the mechanical energy required by the operation. An idea of this can be obtained in comparative experiments with cakes, if the same machine set to the same rate is used by counting the number of revolutions required to crush a certain weight of cakes, and by examining the volume and weight of the pieces falling through the sieve, for the production of flour or meal must be avoided as far as possible.

77 - **A Biochemical Study of Copra Meal.** — SANTOS Y ALVAREZ, F. O. (Laboratory of Agriculture, University of the Philippines), in *Phillippine Journal of Science*, Vol. XVI, No. 2, pp. 181-189, bibliography of 22 works. Manila, February, 1920.

A sample of coprah meal from Manila was ground fine, and on analysis showed the following composition:

	Per cent
Moisture	11.3
Oil	12.2
Crude protein	20.1
Ash	5.5
Crude fibre	13.2
Carbohydrates	37.0

A comparison of nitrogen distribution in the hot water insoluble portion of copra meal with cottonseed meal showed that the latter was richer per cent: — in amides 15.37; in cystine 5.93; poorer in arginine, lysine and non-amino, and nearly identical as regards humin (—.67 %) and mono-amino (0.86 %).

The alkali-soluble protein is the most abundant in copra meal; 47.55 % is the total protein nitrogen soluble in hot water.

This percentage appears to be somewhat low when compared with that obtained by OSBORNE and CAMPBELL who were able to dissolve a total of 96.6 % of the protein nitrogen found in lupin seeds.

Copra meal forms an excellent supplementary concentrated feed fed with green leaves.

78 - **Use of *Opuntia* spp. as Forage.** — See No. 59 of this *Review*.

79 - **Hybrid between *Equus asinus* and *E. Kiang*.** — POCOCK, R. J., in *The Field*, Vol. CXXXVI, No. 3542, pp. 703. fig. 1. London, Nov. 13, 1920.

The Zoological Society in London possessed a fine stallion wild ass from Somaliland, the only country apparently where the African ass (*Equus asinus*) still survives as a wild animal. This differs from the domesticated type in one or two points of secondary importance, notably in the sharp definition of the leg stripes; the obliteration or evanescence of the shoulder and spinal stripes, and the big patch of dark colour on the base behind the ear.

With a view to improving the strain of domestic asses, a number of foals were bred from a cross between the Somaliland stallion and a Castillian specimen. Amongst the cross breds thus obtained was a fine female which stands about 12 hands, but, except for her large size and almost total suppression of the spinal and shoulder stripes, scarcely differs at all from a well-bred English donkey. Being the progeny of two races, the Somaliland and the Tibetan wild ass or Kiang (*E. Kiang*), she gave birth to a foal of quite a distinct species. In body colour it is reddish brown like the sire but in other respects it favours the dam, showing no trace of the sharply defined white on the throat and legs characteristic of the Kiang, the legs being dark grey with a few indistinct stripes. There is about the same amount of white on the belly as in the dam, and the shoulder and spinal stripes are faint; hoofs narrow, ears long. Hitherto all true hybrid Equidae have proved sterile, but it will be interesting to discover if that rule applies to the hybrid in question.

80 - **Intensive Production of Baby Beef in France.** — LAPLAUD (DECHAMBRE, *reporter*) in *Comptes rendus de l'Académie d'Agriculture de France*, Vol. VI, No 33, pp. 795-798, and 802-808. Paris, November 10, 1920.

M. DECHAMBRE laid before the Académie a paper by M. LAPLAUD dealing with the intensive production in France of the so-called " Baby Beef. "

For some time, a movement has been noticeable in the Press in favour of the intense production of baby beef according to the North American method, which would seem to have originated in that country. For over 30 years, France has regularly and systematically raised remarkable baby beef cattle. Since 1882 M. LAPLAUD (père) has been a large producer of these animals.

The Limousin breed has become famous as furnishing baby beef cattle, and the Charolais race is in no way behind M. G. CORMOULS-HOULES, after trying animals of different breeds, such as the Angle, Tarn, Aubrac, Salers, Garonnais, and Gascon breeds chose the Charolais and Limousin breeds, as being distinguished for their early maturity and large net yield of meat.

Yearling Charolais bulls or heifers have been mentioned (which have been fattened the following winter, and sold at high prices in the spring) as weighing on an average from 500 to 600 kg. The district of Nevers sends to Lyons, young pasture-fed bulls, and heifers, of which the smallest and youngest weigh between 500 and 700 kg., when 2 years old. Those that weigh most are despatched to Paris. Young Limousin cattle sold to the butcher and heifers or bulls, 8 to 16 months old, have a gross weight of from 250 to 450 kg.; the bulls are perhaps a little heavier, but the meat of the heifers is the finer. Heifers and oxen of 16 to 24 months and over weigh between 400 and 650 kg.

At Faillades (Tarn), M. G. CORMOULS-HOULES kept every year in his sheds, some 500 Limousin heifers which, when bought at the age of 12 months, weighed on an average 340 kg. He kept them 8 months, and sold them to butchers in Lyon, their average weight then being 560 kg., so that they had gained 915 gr. per day.

M. DECHAMBRE, during his visit to Faillades, estimated as an average of 5180 gm., the daily gain of young heifers weighing on an average 400 kg., and fed the following rations.

Siloed forage	20 to 25 kg.
Bran	1 kg
Cake	1 kg

Comparative feeding experiments were made at Faillades in November, 1895, with 24 Limousin heifers of the average weight of 400 kg. The results are set forth in the following Table.

Feeding experiments with Limousin Heifers.

of lots	Ration consisting of:	Total dry matter in ration	Nutritive ration	Average increase in live-weight per head, per day
		kg.		kg.
Lot 4:4 animals weighing 1 600 kg	22 kg. siloed forage 9 » boiled potatoes 1 » Egyptian cotton cake	10.610	1:6	1.000
Lot 5:4 animals weighing 1 600 kg.	6 kg. siloed forage 6 » dry hay 6 » boiled potatoes 1 » Egyptian cotton cake	10.250	1:5	1.050
Lot 2:4 animals weighing 1 600 kg.	16 kg. siloed forage 16 » boiled potatoes 1 » Egyptian cotton cake	10.300	1:5,6	1.150

M. LAPLAUD (père) has described to the Société d'alimentation rationnelle du bétail, the rations with which he had reared thousands of young stall-fed cattle (dry hay, beets, Jerusalem artichokes, and cotton cake). Barley-meal, rye-flour, maize, groundnut cakes, maize gluten, etc., may also be given. At Dr. de ROTSCHILDS stock-breeding centre at Vaulx-de-Cernay, groundnut cakes and different kinds of meal (barley-meal, bean-meal, etc.) are fed. This system, having long since shown its financial value, has become generalised, and whole arrondissements could be mentioned where only fat cattle are raised for the Lyons, Saint Etienne, and southern markets.

M. LAPLAUD concludes his note by saying that the best French breeds of beef cattle, which furnish very early animals, are the finest in the world, but they do not occupy the place they deserve.

81 - **Feeding Experiment with Yearling Steers. — I. Winter Rations and Their Influence on Pasture Gains. — II. Use of Silage and the Cost of Rations for Wintering.** — SHEETS, E. W. and TUCKWILLER, R. H. (Animal Husbandry Division), in the *United States Department of Agriculture Bulletin* No. 870, pp. 1-20, tables 12, Figs. 8. Washington, D. C., October 20, 1920.

The report of part of a series of experiments that have been in progress since 1914 carried on in co-operation between the Bureau of Animal Industry and the West Virginia Agricultural Experiment Station to study bee-production problems in the Appalachian Mountain region. The steers used in this work were of the grade Shorthorn, Hereford and Aberdeen-Angus breeding, and averaged from 650 to 675 lb., in weight at the beginning of the winter period and were one year old the previous spring. From the analyses it was evident that the feeds used with the exception of cottonseed meal were somewhat below the average in quality.

I — The following Table gives a summary of gains and losses in weight per steer, winter and summer, and the composition and nutritive ratio of the rations fed each year: (See Table page 101).

The conclusions from these results are that: 1) An average daily ration of 19.8 lb., of maize silage + 5 lb., mixed hay + 2.5 lb. wheat straw fed to moderately good steers weighing 663 lb., (Lot 1) for 130 days during the winter should maintain them without loss in weight: — 2) An average daily ration of 23.1 lb., of maize silage + 4.9 lb., of wheat straw, + 1 lb., of cottonseed meal fed to steers weighing 604 lb., (Lot 2) for 130 days during the winter should maintain their weight and allow an average gain of 62 lb., per steer. — 3) An average daily ration of 11.9 lb., of mixed hay + 4.1 lb., of wheat straw fed to steers weighing 665 lb., (Lot 3) for 130 days during winter would not maintain their weight but would result in an average loss of weight of approximately 35, 4 lb. The steers in Lot 2 receiving a protein concentrate in the ration did not lose weight as in Lots 1 and 3. 5) The steers receiving maize silage as part of the ration made greater total gains for the year than those receiving rations of dry roughage alone; the latter which lost weight during the winter, and those fed on a maintenance ration of which maize silage was only a part (Lot 1), made greater gains during the first 2 months on grass than those steers which had made

Lot	Ration	Average quantity per steer daily	Composition: Dry matter	Composition: Protein	Composition: Carbo-hydrates	Composition: Fat	Nutritive ratio	Years	Average gain (+) or loss (—) in weight per steer in winter	Average gain in weight per steer in summer	Average total gain in weight per steer winter and summer

		—	11.23	0.591	5 882	0.245	—	—	—	—	—

considerable gain during the winter; 6) there was a very slight tendency for the steers fed on dry roughage alone (Lot 3) to make less gain during the last 2 months of pasture season than those which had received silage in the ration (Lots 1 and 2) during the preceding winter.

II. — A summary of the comparative cost of the different rations. The maize silage, wheat straw and cottonseed meal (fed to Lots 2) was the cheapest ration used and at the same time the best, making the greatest increase (62 lb.) in weight of the steers. The authors estimate that the addition of maize silage to the ration for wintering yearling steers gave them an increased value of from $ 1.19, to $ 5.79 per head, depending upon the ration used. The feeding methods used in wintering yearling steers added from $ 1.40 to $ 2.85 per cent, to the spring value over the preceding autumn, again depending upon the ration used.

82 – **Field-Peas for Fattening Lambs.** — LONSDALE, T. W. (Manager, Moumahaki Experimental Farm) in *The New Zealand Journal of Agriculture*, Vol. XXI, No. 3. pp. 140. Wellington September 20, 1920.

On many old established holdings the raising of a profitable crop of rape has become somewhat precarious and it has been found necessary to substitute other fodder. The author therefore carried out a short preliminary trial of the fattening qualities of peas and rape respectively. Rape was sown on October 15, and on the same day an adjoining plot of equal area was sown with Partridge peas, both plots receiving similar treatment with regard to preparation and manures. On February 2, a line of crossbred lambs by Southdown rams was divided up and after marking and weighing, equal numbers were placed on each plot These lambs had not received any artificial food previously and had been running on fresh pasture.

The following shows the dates of weighing and average live weight per lamb: —

Lot I (rape) Feb. 2, 58.65 lb.; Feb. 15, 65.80 lb.; Feb. 22, 68.60 lb.
Average gain per lamb, 9.41. lb.
Lot 2 (peas); Feb. 2, 56.35 lb.; Feb. 15, 60.40 lb.; Feb. 22, 69.30 lb.
Average gain per lamb 12.68. lb.
Gain in favour of peas, 3.27 lb. per head.

The lambs on rape made most headway during the first two weeks, but the gain in weight of the lambs on peas during the third and final weeks was remarkable.

Preparations are being made to conduct a similar test on more extensive lines during the present season.

83 – **The Goats of the Mediterranean Countries.** — MANETTI C., in *L'Agricoltura coloniale*, Year XIV, No. 9, pp. 367-376, Florence, September 1920.

In the Mediterranean Basin, the following species of goat are still found in a wild state: —

(1) The Bezoar, Pasang, or Grecian Ibex (*Capra aegagrus*). A tall animal, with a robust body, and sharp horns directed forwards, inhabiting the mountains of the Grecian archipelago, Asia Minor, and Persia.

(2) The Alpine Ibex (*Capra ibex*) with large horns characterised by strong tranverse ridges on their anterior surface, living on the peaks of the Alps and Pyrenees.

(3) *C. caucasica* with brown back and white abdomen, and large triangular horns.

Three races of goats live in the Mediterranean countries (European, Asiatic, and African breeds); and there are numerous varieties of each. The Swiss Alpine varieties, which are the best products of European goat-breeding, belong to the European race.

The white Gessenay variety, orginally coming from the Upper Simmenthal, has a white coat (snow-white or cream) and is usually hornless. Its height is 1.20 m , and its average weight 80 kg: these goats yield 4 to 6 litres of milk daily.

In the Viège Valley, and the Haut-Valais, there is another large-horned. Variety characterised by its variegated coat, black from the head to the middle of the back, the rest being white. Its height is from 70 to 80 cm., and its hair is thick and silky.

The chamois-goat of the Alps is very widely distributed; it lives on the Alps of Suth Switzerland, where it is confused with the Val d'Aosta and Piedmontese goats, animals which it greatly resembles. Its hair is long and silky, of a light-brown colour and it has a longitudinal brown stripe running from the sinciput to the root of the tail. The male has an especially fine coat. The most striking characteristics of this species are its great hardiness in cold places with poor pasturage, and the facility with which it adapts itself to all climates and all regions: these goats are, in fact, as suitable for stall-feeding as for living in the open. Their yield of meat and milk is good.

The Lyonnese goats of Mont Dore belong to another Alpine variety; they live in sheds on the farms, and their rich, abundant milk greatly contributes to the flourishing cheese industry of these regions. They are about 60 cm., high. Their frame is well formed, and their coat is dirty grey or yellowish.

The Pyrenean goats should also be mentioned; they are excellent milkers, and are generally kept in the plains of Béarn, the Basses-Pyrénées, Gers, and Dordogne.

Spain possess 3 much prized varieties of goats, those of Murcia, Grenada, and la Manche, respectively The Murcia goat has a short, sorrel-coloured coat, sometimes with patches of white, chestnut, and black. Its average height is 70 cm., and it is delicately and perfectly shaped. It is a good milker, but its milk is chiefly noted for its high fat content. The Murcian goat is a gentle, good mother, and always has from 1 to 2 kids a season. It is also a very unexacting animal.

This breed has been imported with much success into Algeria, where it has been greatly improved, and has doubled its daily milk yield In France, crossing experiments have been made between this Spanish race, and French and Swiss breeds, especially with Gessenay and Nubian goats. Hybrids with fixed characters and known as the Race of Sainte Geneviève have been obtained. These must be regarded as improved Murcians, both on account of the large amount of fat present in their milk and the good flavour of their meat. Castrated he-goats yield, when killed, about 9 kg., net of fat (melted), which can be mixed with natural butter, owing to its excellent organoleptic qualities.

In Dalmatia, Bosnia-Herzegovina, Montenegro, Serbia, Greece, and Albania, the predominant variety of goats is one belonging to the European Sanson breed, which differs distinctly from all other varieties. These goats are of a dolichomorphic type, and vary in height from 67 to 70 cm. Their skull is brachycephalic, the forehead is broad, concave, between the very prominent orbital arches the face is short, and the nostrils are depressed towards their inner surface.

Lively. light-chestnut coloured eye, lyre-shaped horns with transverse ridges which, however, sometimes form a spiral with very wide volutes. Their frame is very strong and shapely. The udders are large, pendent, well formed, and pyriform although the points of attachment are rather large, the teats are regularly arranged, and a little inclined outwards. The hair is very fine and silky. The coat is ashen-grey, but some goats have black, chestnut, very white, and spotted coats This animal is a a good milker and its meat is excellent. The breed is very w ll adapted to rugged, mountain land, its chief quality is extraordinary thriftiness, but in spite of this, it has excellent milk and meat producing qualities.

This variety of goat is found throughout central and south Italy; in the latter part of the country it is mixed with the Maltese breed. All the goats of north Italy belong to Alpine varieties.

In Turkey in Europe, on the West coast of Asia Minor, in Bulgaria, and Rumania, a variety of goats is kept that belongs to the Asiatic SANSON race. They are not tall, dolichocephalous, with rectilineal profile, and elongated elliptical faces Their ears are long and pendent, horns are usually, absent, or replaced by small appendages. The absence of beard under the chin is characteristic in the male. The hair is short, reddish, with patches of black or chestnut and white. This breed is known as the Anatolian.

The Mambrine variety is also excellent and it too belongs to the Asiatic race, which is found in Syria, Persia, Armenia, Palestine, Upper Arabia, and as far as the peninsula of Sinai. There are the two following sub-varieties:—

(*a*) The Meress or Damas goat, with brownish-grey, black, or white coat.

(*b*) The Samar goat, which includes a hornless type known as the "Gara," with black, glossy coat and some reddish patches on the face.

These animals, which are 80 to 90 cm., in height, are characterised by excessively long ears, which sometimes measure as much as 30 cm., in length, although they are scarcely 15 cm., wide. The hair is 25 cm., long and is used locally mixed with sheeps wool for making stuff and carpets. The female is very prolific, bearing kids twice a year, usually, between December and January and between May and June.

The lactaction period is fairly long, even after parturition, and a well-fed goat gives 3 to 4 litres of rich milk daily, which is used for making butter and cream cheese. Aleppo butter is specially prized by the Arabs of Syria. The Mambrine goat is a triple-purpose animal producing hair milk, and meat; the meat has an excellent flavour, and is much liked by the natives. It is a cosmopolitan animal and very well acclimatised to Egypt and Algeria, whither it has been imported, and where it has played a part in improving the native breed.

Amongst the other Asiatic goats living in regions near the Mediterranean, mention may be made of the *Shamy* variety which occurs in Mesopotamia. The *Kurdi* variety is distinguished by its long, narrow ears, which, however, are not so long as those of the Mabrine goat. This goat also lives between the Tigris and the Euphrates, and differs from the former in having shorter ears and thicker coat, of which the hair is however, coarser These two varieties crossed together have produced a hybrid called *Bedui* but of which the characters are not yet throught fixed. Under the name *Merese*, the natives understand the hybrids obtained by crossing Angora goats with different varieties of goats from Syria and Mesopotamia. These hybrids yield a very fine quality of wool known as mohàir.

In Georgia, Daghestan, Persia, Beluchstan, the Isles of the Grecian Archipelago, and even in Crete and Cyprus, the *Bezoar* or Grecian ibex is still found wild, but it is of no value from the stock-breeding point of view. Two domestic species greatly resembling it live in the Caucasus and in Daghestan; they are chiefly valued for their coats.

The Daghestan goat, which is about 60 cm. high, has a grey coat with very long hair (35 cm); the meat and milk are little appreciated on account of their rank odour.

The Caucasian goat has a grey, reddish, or spotted coat, and is easily recognised by its long horn directed upwards for their whole length and curving inwards at the tip in a single whorl. The milk of this goat is richer and more abundant than that of the preceding varieties, and is used for making butter and cheese; its meat is also excellent, but its coat is the most valuable part of the animal, for 2 skins yield nearly 2500 gm., of hair. This goat-hair is used in Anatolia and Armenia in the manufacture of carpets.

Of all the goats of Western Asia, however, the Angora is the most improved variety. This variety is kept in Anatolia, and especially in the Provinces of Brousse, Costamuni, Sivas, Van, and vilayet of Konia. The natives refuse to sell stud animals of this breed to foreigners. The Angora goat is small, scarcely 60 cm. in height. The horns of the male are long with a helicoidal surface, and the ears are long and pendent. The coat is very valuable and consist of tufts of smooth long hair, sometimes crimped or frizzed. The hair is white, long, and silky, and mixed with down; it falls naturally in the spring, but the animal is shorn in April or May and the coarse hairs are removed with the aid of a wooden comb. The hair is used in making fine materials and especially in the manufacture of mohair. Some selected threads were formerly used in making Utrecht. The hair of the male is more abundant but coarser than that of the female; castration improves the quality of the coat. Although the udders of the Angora goat are small, the milk is abundant and very rich in fat; it is used in the manufacture of cheese. The meat is very delicate and much relished in Turkey, where before the war it used to sell at 3 piastres (0.60 fr., at par) per kg., The *Angora* goat is satisfied with poor pastures, where the vegetation consists for the most part of shrubs and steppe plants, and this variety has even become acclimatised to the saline soils of the plateaux of central Anatolia, where no other variety can thrive.

Angora goats are distinguished according to sex and age by the following names:

(1) Oglacks: kids up to 1 year of age.

(2) Tchebichs; kids above 1 year, old, but less than 2.

(3) Erketchs;: adult males reserved for breeding purposes or shearing.

(4) Damisleks; adult females above 3 years of age, and being triple-purpose animals (producing milk, meat and hair). The hair yield of these animals is 375 gm., in the case of the Ogloacks, 500 gm, in that of the case of the Tchebechs, and 1 kg, and 700 gm., respectively in the ease of the Erketschs and Damisleks. The value of the hair naturally varies according to the individual, and as a rule it is the males that take the palm for the beauty and quality of the hair, which should be white, glossy, and flexible to the touch.

The Angora goat is quiet and thrifty, but must be partially fed, especially in winter; for this reason, the shepherds prepare, in addition to the ordinary straw, reserves of siloed forage kept in simple holes dug in the groun dand covered with planks, soil and stones. This silage consists of the common plants of the plateau pastures mixed with vine-leaves, branches, oak twigs and other roughage, which however, the goats eat with avidity.

The Angora goat industry is very remunerative to the natives, seeing the large demands for the products and their high prices as compared to the low cost of production.

For a long time, attempts have been made to acclimatise and breed. Angora goats in Europe, but although stud animals have been imported for the purpose, no important results have been obtained.

On the other hand, these animals have been reared with conspicuous success in Cape Colony and the Transvaal, where there are now over 2 million head, and they tend to increase to such an extent as to threaten to become serious rivals of the Angora goats in Anatolia itself. It is reckoned, that Cape Colony annually exports 11 million Angora goat skins.

These goats have also been successfully reared in the United States, especially in Texas, New Mexico, California, Nevada, Florida, Oregon, and Louisiana, Australia has also begun to breed Angora goats, and has found it very profitable.

The author advises this breed for Libia and especially for Cyrenaica. In the north coast of Africa, the African breed of goat is found; this is composed of several varieties some of which are very important economically, both for their great thriftiness and their resistance to all the changes of climate.

The Egyptian goat is a variety of the African breed. It is not tall (0.60 m.) ; it is dolichocephalic, and has long, broad, pendent ears. The female is nearly always hornless, and the horns of the male are very small. The forehead is concave, the orbital arches are not prominent, the head is light, the thin neck has a depression where it meets the withers; the body is slim, and the legs are slender.

The good qualities of this breed are its gentleness, large milk yield, and extraordinary thriftiness, which enables it to live on land where other animals would starve. The Egyptian goat is not a great wanderer and does very well in the shed. It coat is fawn-coloued with chestnut patches, and its short hair is of no commercial value. The meat, however, is excellent.

The following native varieties of goats are also found in North Africa: Tuoareg; Fouta Djallon, Sokoto Haoussa (Central Africa): Soufo or Touggourt (E. Sahara Constantine); Nubian; Maltese; and also the Libyan, Tunisian, Algerian, and Moroccan varieties.

The Touaregs breed a short haired goat with black, white, yellow, or spotted coat, which is much valued as a milker, and because it is not exacting as regards food.

At Fouta-Djallon (French West Africa) there are goats still smaller than those previously mentioned, and characterised by their wheat coloured coat and a dark chestnut dorsal stripe like that of a mule.

The small goat reared in Haoussa are white, spotted with black; they give very little milk. The goats of the White Nile are black; they still live in the wild state and are of no interest from the point of view of stockbreeding. They have been imported into Europe and America as ornamental animals for parks.

The Nubian goat must be mentioned, especially for its milk yield. It may be regarded as the ancestral stock of all the other varieties of goats bred on the Barbary coast.

It is not tall, the outline of the head is cyrtoid, and the ears are flat wide, long and pendent. Its specific characteristic is accentuated prognathism. The female is hornless and the horns of the male are small. This goat is especially suited to hot, dry climates, and does not thrive on mountains or damp pastures. The female is very prolific, and bears young twice a year, giving birth to 2 or 3 kids at a time. The Nubian goat is an excellent milker; the milk has a high fat content, and is free from the rank smell characteristic of the goat.

The Maltese goat belongs to a variety of the Nubian breed but has become very distinct from it, which shows the influence exerted by environment upon shape. There are in fact, in all the coast regions of Barbary, numerous varieties of the Maltese goat which, in their turn, differ greatly from the original type. The Maltese animal is not tall, its neck is slight and long, body elegant and slender, legs fine and straight, with regular action, The coat is white, or sorrel, or has reddish-white patches. The hair is long, fine and silky; the chin beardless; the horns are small. The Maltese goat can be kept in the stall or in the open. It eats less than the Arab goat, and yet yields more milk; in the height of the lactation period, it gives as much as 3 to 4 litres daily. Its meat is excellent and preferred to that of other goats, owing to its .low price and freedom from rank smell. The Maltese goat is very prolific; it can bear young twice a year, and has 2 or 3 kids each time. It is of a gentle disposition, and easily led; if kept in the stall and well fed, its milk yield is considerably increased. In Libia, the most common varieties of goat are the Nubian crosses between the Nubian and Maltese breeds, commonly known as Arab goats, and the Maltese. The last mentioned varieties are chiefly found near centres of population, while the first-mentioned compose the large, travelling herds of the interior.

The Kabyle goat is met with in Tunisia and Aures, its hair is long and flexible, and its horns well developed. Its milk-yielding capacity is but little developed, and its milk is not very sweet, having a strong unpleasant odour though the fat content is high. There is also a hornless sub-variety of the Nubian, which is known by the name of Arab goat. It stands higher than the preceding animal and gives more milk.

Along the whole coast running from Tripoli to Algiers, by way of Tunis, numbers of goat-breeding centres are to be met with. There, Maltese goats, as well as other breeds and varieties are reared, mostly, however by Europeans, for Arabs rarely keep these animals, having a traditional and natural repugnance to them. At the present time the introduction of Maltese goats into Algeria, Tunisia and Morocco is prohibited under heavy penalties, for it was believed that their milk serves as a means of transmitting *Micrococcus melitensis*, the pathogenetic agent of Maltese or Mediterranean fever. More recent investigations have, however, shown that this disease is now endemic in all the basin of the Mediterranean, and that it is very possible that it is transmitted also by goats of other races.

In Algeria, as has been said, there are also specimens of Angora and Spanish goats. The latter are chiefly bred in the Department of Oran and throughout Morocco; the varieties most frequently found are those of Murcia and la Manche.

84 - **Precautions to be Taken in Natural Incubation.** — RASQUIN, M., in the *Revue avicole*, Year XXX, No. 10, pp. 5-7, Paris, October 1, 1920.

There are many reasons for failure in hatching-out chickens, and therefore it is a most necessary to neglect no precautions.

(1) One of the first of these is the destruction of any vermin infesting the sitting hen, otherwise, she may frequently leave or even desert the nest, and thus prevent the eggs hatching. In order to destroy these pests, a provisional nest lined with hay is made: in this are placed some china, or plaster eggs. The whole body of the fowl is covered with pyrethrum powder by blowing the latter over it with the aid of small bellows.

The fowl is then placed on the prepared nest, and after 24 hours she is removed to put her on the sitting of eggs in the regular nest. The first nest, which contains all the vermin, is burnt.

Afterwards, it is advisable to provide the sitting hen with a dust-bath consisting of fine cinders mixed with flowers of sulphur or a little pyrethrum powder.

Some poultry-breeders, on detecting the presence of vermin, fill an empty egg-shell with a piece of sponge soaked in encalyptus oil and lay it in the nest.

(2) The sitting of eggs, whether sent by rail or otherwise should not be put under the hen as soon as it arrives. On the contrary, the eggs must be left quiet for 24 to 25 hours, in order that the germ may regain its equilibrium and during this time the eggs should be turned at least twice.

Special cardboard-boxes, with partitions, are sold relatively cheaply for setting of eggs, which do much better in these boxes than when wrapped in paper or packed in saw-dust peat, or cereal-chaff for if the journey is of any length, these may impart an odour to the eggs which may have disastrous consequences.

(3) Another matter to which little attention is paid is the cleanliness of the eggs during incubation. Sitting hens that sit too closely often leave droppings on the edge of the nest. In this case, the soiled eggs should be cleaned and washed in tepid water, and then properly dried. Even if one egg should be broken in the process, the rest must be washed all the same. To neglect these precautions is to risk the proper development of the embryo and may entail the loss of the chick.

(4) The sitting hen should be watched during incubation to see if she goes out every day, returns to her nest, etc. Care must be taken to feed her well as for instance with a paste made of wheat, buckwheat, or barley, boiled potatoes mixed with milk, etc From time to time, some earthworms ought to be collected and given to the hen. The hen must always have a supply of food and drinking-water at hand placed in a fixed place, so that the work of supervision may be lightened.

(5) If several hens are sitting in the same place, care must be taken to separate them by proper partitions.

(6) Finally it is advisable not to put more eggs under a hen than she is able to cover; from 12 to 15 is the maximum to be given to an average sized fowl. Otherwise, the other eggs do not receive sufficient warmth, and those in the centre, when the hen pushes them to the outside with her beak, get too cold, which is fatal to good results.

Further, if the hen feels too many eggs beneath her, she distends her wings over much, and in this way the necessary warmth escapes.

85 - **Cost of Feeding Pullets up to the Age of Six months Old.** — BROWN, F. C., in *The New Zealand Journal of Agriculture* Vol. XX, No. 6, pp. 371, Wellington, June 21. 1920.

The trial test was conducted at the Milton Poultry Station at the request of the New Zealand Poultry Association with 29 pullets and 24 cockerels, all white Leghorns. The cockerels were separated from the pullets when they had attained a weight of about 3 ½ lb., and the available marked price was credited to the pullets, and the whole cost of feeding was charged against the latter.

The following are particulers and actual cost of food supplied to the chickens during the 6-months test:

	£	s.	d.	£	s.	d.
Whole wheat, 1008 lb., at 6s. 8*d.* per bushel				5	12	0
Cracked wheat, 187 lb., at 6s. 8*d.* per bushel	1	0	9			
Add cost of cracking	0	1	6			
				1	2	3
Crushed wheat, 112 lb., at 6s. 8*d.* per bushel	0	12	5			
Add cost of crushing	0	0	9			
				0	13	2
Pollard, 769 lb., at £9, 5*s*. per ton				3	11	2
Bran, 254 lb., at £7, 5*s* per ton				0	18	5
Oatmeal, 26 lb., at 6*s*. 9*d* per 25 lb. bag				0	7	0
Hulled oats, 264 lb., at 4*s*. per bushel	1	6	5			
Add cost of hulling	0	6	7			
				1	13	0
Rolled oats, 45 lb., at 35*s*. per 100*lb*				0	15	9
Meat meal, 21½ lb., at 20*s*. per 100*lb*				0	4	4
Total . . .				**14**	**17**	**1**
Deduct price realised for 24 cockerels sold at 4*s* each . .				4	16	0
Net total cost . . .				**10**	**1**	**1**

The average net cost of food for one pullet works out at 6*s*. 11 ¼*d*.

86 - **Control of Foulbrood.** — I. Phillips, E. F. The Control of European Foulbrood in *The United States Department of Agriculture, Farmers Bulletin* 975, pp. 3-16, Washington, D. C., July 1918. — II. Idem. Control of American Foulbrood in *Farmers Bulletin* 1084, pp. 3-15, figs. 5. Washington, D. C., March 1920.

I. — European foulbrood (1) caused by the *Bacillus pluton* varies distinctly from the American disease and it is essential to ascertain which type is actually prevalent before applying treatment. The fact that in many cases both types have been considered manifestations of one disease has led to a spread rather than eradication, owing to lack of proper differentiaton in treatment. The most accurate method of diagnosis is by bacteriological examination, but when this is unavailable, a detailed study of the symptoms is important.

The larva is usually attacked at an early stage of development, while still curled up at the base of the cell. The earliest indications of disease are a slight yellow or gray discoloration, and uneasy movement. The larva

---

(1) See *R*, Aug. 1912, No. 1202. (*Ed.*)

becomes slightly translucent and gives a clearly segmented appearance. The position of the larvae is one of the best means of differentation between the two types of disease. In American foulbrood the larvae are almost without exception found on the lower side wall, while in the European type, they may be there or at the base of the cell, or on any of the side walls even the upper one. As decay proceeds with the latter, the colour changes to yellow or gray, and the translucency is lost. This may be taken as the chief characteristic of the disease. Finally, all that is left of the larva is a yellow or grayish brown scale against the base of the cell or a shapeless mass on one of the side walls. The decaying mass behaves like a rubber band which has lost elasticity and breaks when streched and is entirely dissimilar to the fine ropelike condition observed in dead larvae of the American foulbrood.

The disease attacks drone and queen larvae nearly as quickly as those of the workers.

Colour is the most constant symptom, but otherwise there is distinct variability.

Preventive measures. — It is far more important to prevent the disease than to eradicate afterwards. The use of resistant stock is therefore urgent. The use of strong rigorous, three banded Italian stock has been found the best, but a careful selection of the breeding queen has to be made.

Strength of colony is equally important, as this is a disease of weak colonies, and also care should be taken in the proper wintering of the bees. If remedial measures are found necessary, it should be noted that control methods used are exactly the same as those used for swarm control. Either the queen or the brood is removed or they are separated within the hive.

II. — American foulbrood caused by the *Bacillus larvae* attacks colonies of all strengths and at any season of the year when the bees are active. Once in the hive it will remain until the colony is destroyed or the disease effectively treated.

The first indication is the slight brownish discoloration and the loss of the well rounded appearance of the normal larva. The chief symptoms are in the outward manifestation being simply the appearance of the larvae or pupae after death. The comparison with the effects of European foulbrood have already been noted. Usually the disease attacks only the worker brood, and only in rare cases the queen and drone brood. The disease appears to spread more rapidly during a honey flow; all races and strains are attacked. Bacteriological observation has proved that the *B. larvae* is a specific spore-bearing organism which causes this disease to be entirely distinct from all other diseases of bees.

Preventive measures. — No system of management of the apiary has yet been found which will prevent the entrance of American foulbrood. In this respect the disease differs greatly from the first mentioned type. At present, the only advisable proceedings known lie in the observation of precautions which can prevent the bees from getting the honey from diseased colonies.

The actual remedial treatment should be confined to the stoppage of further devastation by removing all material capable of transmitting the cause of the trouble, and not to save the larvae already dead or dying Details are given as to the " shaking " treatment and other treatments at present employed. Box-hives are not advised on any account. The author states also that drugs hitherto recommended are not of the slightest value.

87 - **Pisciculture in Switzerland in 1919.** — *Bulletin suisse de pêche et pisciculture*, Year XI, No. 5, pp. 58-61. Neuchâtel, May 1920.

The following information is astracted from a Report issued by the Swiss Département fédéral de l'Interieur (1).

In 1917-1918 and in 1918-1919 respectively, 203 and 216 breeding stations were working during the incubation period, and 163 768 000 incubated eggs produced 127 785 000 fry. During 1917-1918 and 1918-19, respectively 133 300 095 and 126 863 037 fry were placed in public waters, inclusive of 142 037 fishes of 1 summer or 1 year.

The fry produced by incubation were as follows: —

(a) *Native species* :—	
Salmon	961 000
Salmon-Trout	175 000
Lake Trout	3 850 000
River and Brook Trout	9 415 000
Salmo alpinus	3 907 000
River Charr	1 717 000
Coregones	91 650 000
Pike	15 506 000
(b) *Foreign Species*: —	
Fountain Salmon	591 000
Rainbow Trout	13 000
Total . . .	127 785 000

The Confederation granted 34 700 fr. in 1918 and 39 700 fr. in 1919 to the Cantons for pisciculture, chiefly for raising the fry and stocking the waters.

As the Canton of Valais did not ask for a grant in 1919, no information is at hand concerning their activities. · See table, p. 113.

88 - **Toxic Action of Ingested Linseed Meal on Trout.** — ALMY, L. H., and ROBINSON, R. K., (Bureau of Fisheries United States Department of Commerce, Washington) in *Journal of Biological Chemistry*, Vol. XLIII, No. 1, pp. 97-111, bibliography of 8 works. Baltimore, M. D., August, 1920.

Recently at a commercial hatchery in Rhode Island, a disease broken out among brook trout of 1 and 2 years. The fish turned black, moved convulsively, many of them became blind and large numbers died. It was

believed that the disease was connected in some way with the replacement. of a mixture containing cottonseed meal which had formed part of their food, by linseed meal.

The observations and experiments here recorded were made at the commercial hatchery in Rhode Island and at the United States Government hatchery in White Sulphur Springs, West Virginia.

The following points were made clear: 1) That of the two vegetable meal linseed and cotton seed, the linseed meal alone was responsible for causing the change in pigment, blindness, and death; 2) that the causative agent is contained in the non-oil constitutents of the linseed meat; 3) that linseed oil in the food of trout has a slightly intoxicating effect upon the fish; 4) that fish thus affected can be brought back to a heathy condition, except as regards pigmentation and blindness, by a diet of some fresh meat product; 5) that yearling trout fed for 3 months on a diet of hog lungs gained in weight three times as quickly as those receiving the cereal meal mixtures; however, a 3 times greater gross weight of food was consumed in the former case than in the latter. Consequently, a mixture of red dogflour and meat meal is not an adequate substitute for the fresh, packing house products ordinarily used as food for trout.

The injurious effect of ingested linseed meal upon brook trout is due in a large measure to hydrocyanic acid which is present in most linseed meals as the result of the hydrolysis of a cyanogenetic glucoside. The nervousness, pigment change, and blindness are all believed to be attributable to the action of the hydrocyanic acid on the nervous system of the trout. The observations here reported indicate that this action results in an impaired vision, and a consequent interference with the control of the movement of the pigment granules in the chromatophores of the skin, this control normally being obtained by means of stimuli received through the eyes by way of the central and sympathetic nervous systems.

FARM ENGINEERING.

89 - **New Agricultural Implements.** — LARUE, P., in *La vie agricole et rurale*, Year 9, Vol. XVII, No. 45, pp. 278-279, figs. 3 Paris, Nov. 6, 1920.

COMBINED SEEDER AND FERTILISER DISTRIBUTOR. — Economy of fertiliser and more early growth are obtained when the fertiliser is spread in a line in the furrow. For this purpose, a wheel-barrow seeder and fertiliser-distributor has been evolved for market gardening.

A sprocket on the axle drives the fertiliser distributor and the seeder by a bicycle chain. The roller is double and so formed as to leave a raised line of open soil in which the germinating seed can grow freely. The fertiliser distributor is set to use about 11 lb., of fertiliser per acre, the lines being about 1 foot apart.

For seeding, half-a-dozen interchangeable grooves or perforators are provided for different sizes of seed. A tracer guide enables the correct distance to be kept between the lines; it is fitted at the rear, the horizontal bar resting on the vertical supports of the handles.

A HARROW SEAT. — This seat is not a permanent fixture to the harrow, but is a separate attachment mounted on two wheels, drawn by two shafts that pass over the harrow and whose ends are fixed to the wide swingletree that joins the front portions of the harrow.

NEW HARROW TINES FOR MEADOWS. — These tines, invented by WILDER, are designed to avoid the usual fault of easy clogging, and are freer than usual whilst preserving the suppleness of the tines as a whole. They are made in groups of three joined by curved members, as is shown in the accompanying figure. The outer members are joined by chains.

Too little harrowing has been done in meadows, although the operation is said to double the crop.

The harrow can be reversed to increase the life and it can be used to cover light seeds by unhooking.

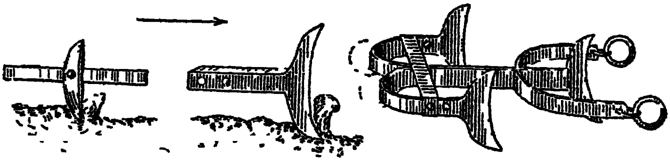

Fig. 1. — New harrow tines

DRAWBAR PULL ON HARROWS. — The agricultural Station of Iowa has recently conducted dynamometer experiments on the breaking-up of oats and maize in sandy soil. Disc harrows (weighing from 5 cwt., to 6 cwt.,), with complete discs required a smaller tractive effort than those with hollow discs, although these were lighter There was little difference when the axis of the discs was perpendicular to the pull. The width worked by the harrow was 9 ft. 9 in., and the depth from 2 to 4 in., and a speed was maintained of 2 ½ 3 m. p. h. usuing from 3 to 5 H. P.

An ordinary square toothed harrow going over lightly after ploughing and with 2 sections 1.5 metres wide, 2-4 h. p. is required to work at a speed of 2 ½ m. p. h. In the second case, two sections were placed in tandem behind the first two, thus giving a double harrowing.

MACHINE FOR SPREADING LIQUID MANURE IN FURROWS — The inventor of this machine, PLATH, has overcome the difficulty of speading liquid manure evenly, another difficulty being that it may evaporate both in the liquid above and on the soil. The idea consists of three hollow tines which are connected to the tank by flexible tubing, the feed being by gravity. A strainer must always be used when fiilling the tank. In this way the liquid manure can be spread in the furrow, so that watering, manuring and tillage are carried on simultaneously. To ensure even distribution, the hermetically closed tank always works at a constant height of liquid. A small liquid manure distributor with two small tines is also made. The liquid manure should be diluted to decrease its alkalinity, with the help of a hygrometer which indicates the approximate content of nitrogen, the content of potash being assumed to be in proportion.

Automatic uncoupling device for tractor ploughs. — A Wisconsin engineer has patented a design of coupling for mechanical-traction ploughs, by which, when the plough strikes a boulder or other obstacle the engine is automatically stopped, the supply being cut off.

Fertiliser distributor. — The fertiliser distributor has followed too closely on the lines of the seeder, and attention is now being paid to spreading by means of centrifugal force. In America, machines are now made to fix behind a cart containing the fertiliser in a loose state. A horizontal revolving endless screw crushes the fertiliser and throws it out over a width about 3 feet. The Duplex model of this machine weighs about 1 ½ cwt.

A new tillage machine. — This machine has been designed by the Société d'etudes pour la construction de machines agricoles to decrease the strain which is put on the wrists and arms when using the ordinary hand type, by using the shoulders instead. The small working members are mounted on a beam suspended from a wheeled pole that ends at shoulder height. The two hands are placed on a guide by which steering is effected.

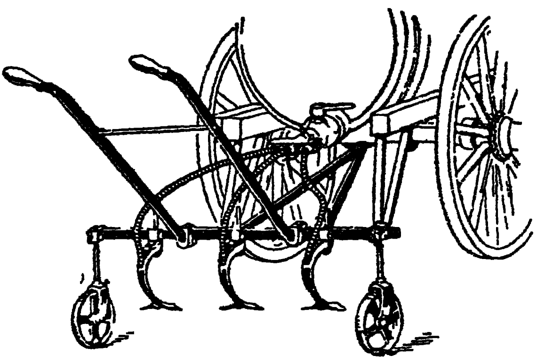

Fig 2 — Liquid manure distributor for furrows

A Pivoted Auxiliary Plough Beam. — The English " Pidsea " plough is designed to overcome the difficulty which occurs in gang ploughs, where the plough bodies are parallel to the beam but not always to the soil, and where the shares may do little work owing to undulations of the ground.

Each plough body has an auxiliary beam articulated vertically with the main beam by 2 connecting rods, the whole forming a sort of parallelogram. A roller fixed under each auxiliary beam and bearing on top of the blade, prevents any tendency to rise and makes the ploughs follow the rise and fall of the ground, but always at a constant depth. It remains to be seen whether the machine is as rigid as the old type, especially when turning.

Supplementary hay carrier. — This supplementary carrier, called the Roberts, and made in England consists of three rows of steel uprights, joined by rope and mounted on a frame which may be put on top of farm carts or lorries. It is very light and strong and greatly increases the carrying capacity of the vehicle.

A HORN SPLINT. — Malformation of the horns of draught cattle is an impediment to driving. In the Garonne valley, where the horns of the Garonne cattle turn down, these horns are sawn off. To avoid this, J. BORGY, a Swiss gentleman, has invented a splint or tube which forces the horn to grow in the right direction.

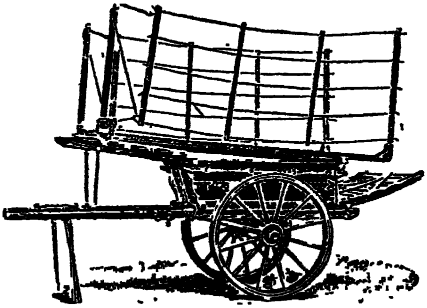

Fig. 3. — ROBERTS hay carrier

90 - **A New Hay-Loader.** — MANRIN, G., in the *Journal d'Agriculture pratique*, Year 84, No. 42, pp 316-317, figs. 2 Paris, Oct., 14, 1920.

This new hay-loader does away with the swaying of the two-wheeled type of machine. This four-wheeled machine, called the " International" is marketed by LA COMPAGNIE INTERNATIONALE DES MACHINES AGRICOLES, 155, avenue du Général Michel-Bizot, Paris, 12^o.

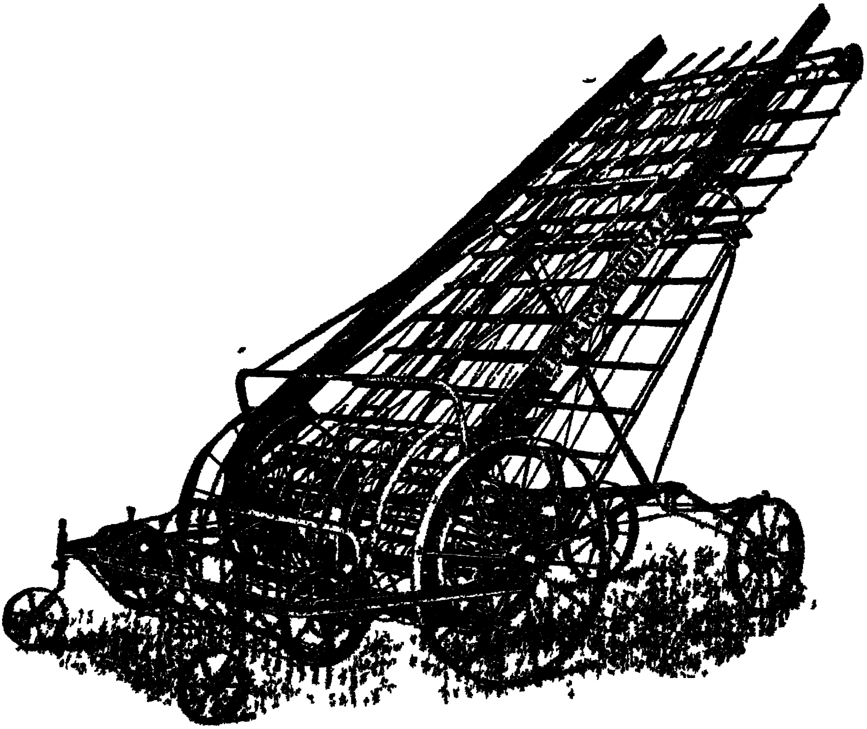
The illustration shows the general design of this model. It is steel built throughout, and is mounted on four wheels, the front ones being pivoted, so that the machine can be hauled either behind a cart or waggon.

The main hay guides are somewhat narrower at the top, so as, to load the hay on the centre of the vehicle, making it easier for the man to spread. A compressor consisting of long springs, holds the hay on to the ledges and chains of the elevator, the tension being easily regulated.

Behind the elevator is the " floating " or " detachable " cylinder, consisting of a metal frame carried by two wheels that can turn horizontally. The frame supports a lattice collecting drum whose radii are furnished with flexible teeth, set at about 3 in., apart. The cylinder, 7 ft. long, is driven by a chain which is kept well away from the hay. About 6 ft 6 in., is covered by the machine, and with 2 or 3 men on the cart a ton of hay can be loaded in about 5 minutes.

91 - **An Automatic Indicator of the Humidity of Cereals.** — CHOPIN, M., in the *Comptes rendus de l'Académie des Sciences*, Vol. CLXXI, No. 18, pp. 860-862, figs 1. Paris, Nov. 2, 1920.

The practice of cleaning wheat by damping followed by rapid drying as well as the influence of the moisture content on the results of melting make it useful to know the content. The author of this article has per-

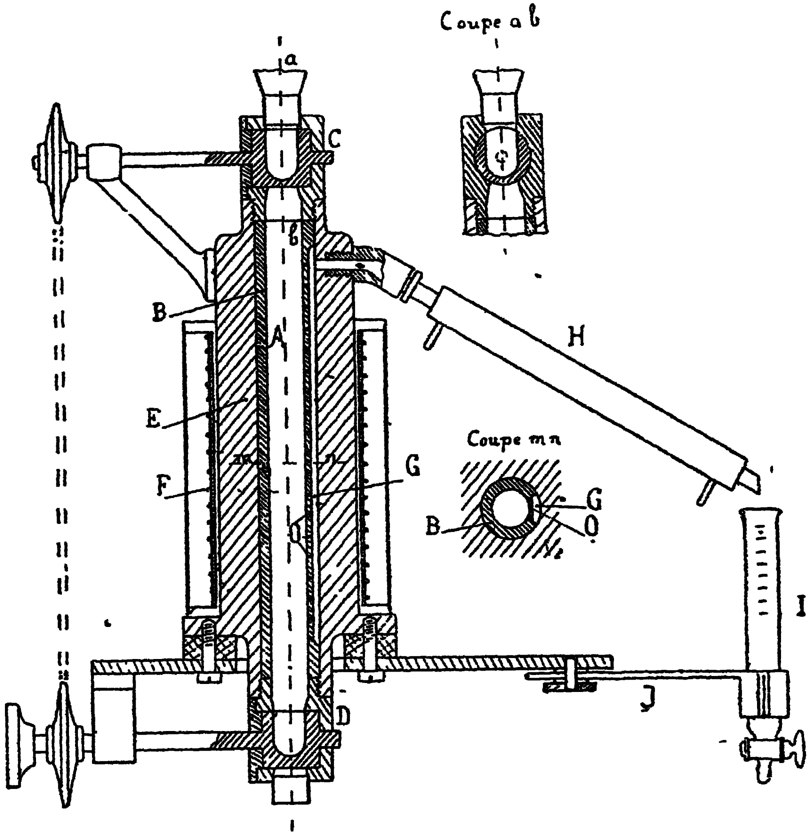


International hay loader

fected an instrument which automatically analyses the humidity of cereals as well as of substances in a powdered or granulated state, samples being taken continuously

The drawing here given shows the essential parts of this apparatus *A* is a cylindrical heating chamber that fits into the socket *B* The top valve *C* acts as the inlet of the grain, etc., and the bottom one *D* as the outer both valves measuring the volume, and slowly rotating so that the holes allow a free passage at regular intervals. As the inlet valve *C* is of slightly larger capacity than the outlet *D*, the cylinder is always kept full; the outward delivery is controlled by *D*.

The cast-iron outer jacket *E* is wound with an electric resistance *F* for heating, which is regulated by a temperature regulator A longitudinal groove *G* connected to the cylinder *A* by small holes *O* conducts the vapour to the condenser *H*; the condensed water can be collected alternatively in two test-tubes such as *I* gratuated in % of moisture, and carried by brackets *J*. The collecting tubes are rapidly substituted one for another under the condenser opening by an electro-mechanical device (not shown in the figure) controlled by the movement of the valve. The result is that the indications given by the machine are, within practical limits, not dependent on the speed of rotation, as the water collects in the tube not in a constant time, but during a determined number of rotations of the emptying valve. Thus, in the machine, a current of wheat flows at a constant rate through a chamber whose walls are kept at a temperature sufficient to dry the wheat almost completely, but not such as to cause a loss of volatile matter.



Automatic indicator of moisture content.

Under these conditions the quantity of steam given off in a given time by the wheat evidently represents its moisture content. The only source of error lies in the substitution of weighing by volumetric estimation, whereby the apparent specific gravity of the torrefied wheat becomes of importance.

Natural wheats were found by the author to have sp. gr between 0.70 and 0.80 so that the sp. gr. of dried wheat lies between 0.63 and 0 67. The resulting average error is therefore acceptable.

This apparatus, installed at the Grand Moulins de Nancy, has been working continuously since August 1919. During that period, the constant of the machine remained invariable, in spite of having been cleaned internally every month. Preliminary tests of 18 varieties of natural wheats or wheats that had received different treatments showed that there was a very satisfactory correlation, between the moisture content and the weight of water collected.

The average error calculated as a percentage of the weight of water condensed was 2 % and the maximum deviation observed was 4.4 %.

This apparatus can be used for other substances and mixtures and for the continuous estimation of constituents other then water

.RURAL ECONOMICS

92 - **The 1921 Wheat Crop in Great Britain.** — MIDDLETON, Sir T., in *The Journal of the Ministry of Agriculture*, Vol XXVII, No 5 pp 421-427 London, Aug, 1920

There is a widespread impression not only that the British wheat grower contributes a trifling amount to the total food supply, but that any effort made to increase the wheat crop would have negligible results. The author however disagrees and lays stress on the importance of home grown wheat and the fact that this contributes more to the food supply of the United Kingdom than any other farm product, with the exception of milk and potatoes.

Estimations as to the nation's resources were made during the war, and it was then discovered that about 42 % of the food was home produced, the chief items in this percentage being: dairy produce 8.3; potatoes 7.4, wheaten bread 6; beef 4, and meat of all kinds 10.5 About 5 million tons of imported feeding stuffs were used in stock feeding, and if the amount of meat and milk made from these is subtracted the total percentage derived through meat and milk from native soil would be reduced to 16.

If 78 % of the cultivated land is required for the production of meat and milk which between them provide about 42 % total food stock from soil, it should also be noted that wheat occupies 4 % only of the cultivated land, and wheaten bread accounts for 16 % of the stock of food grown on the soils. Wheat offals and straw also contribute to the meat and milk supply; before the war less than 70 % of the grain was made into bread. Hence the importance of growing more wheat. The land even now devoted to this purpose produces seven times as much food per acre to that employed in stock farming

The change in the relationship between producers and consumers is very marked since the war, and an increase in home supplies is obviously essential. The rise in the cost of American wheat which has taken place during the last few months is due to a cause which has a peculiar significance for the British farmer. The total wheat crop of Canada, the

United States and Argentina 1909-13, averaged 28 200 000 tons; in 1915, 44 100 000 tons, and an average production 1915-19 of 33 520 000 tons, and last season's harvest, 36 700 000 tons. The American effort made up for the loss of the Russian crop. It should however be noted that in 1920 the United States practically returned to its pre-war acreage and the total yield expected is 22 000 000 tons as against 25 600 000 last year and 18 700 000, 1909-13.

But the United Kingdom is the greatest purchaser of wheat and the United States grows all the wheat she needs and a little more. There is therefore evident necessity in developing the supplies in the former country, now freed from war conditions and limitations. Extensive autumn sowing has therefore been urged.

93 - **Cost of Artichoke Cultivation in the Roman Maremma in Italy.** — See No. 60 of this *Review*.

94 - **Economic Situation of Peach Cultivation in the Department of Casoria (Naples)** (1). — LANDI, R. (R Scuola superiore di Agricoltura, Portici), in *L'Italia Agricola*, Year LVII, No. 8, pp. 233-242. Piacenza, Aug 15, 1920.

For some years now, peach growing has been gradually replacing the cultivation of herbaceous plants except flax in the arrondissement of Casoria.

The author describes the poor methods used in the region, the result being such a degeneration that the life of the peach trees is now only 8 to 10 years whereas formerly it was from 15 to 18 years.

The cultural accounts of a plantation of peach and walnut trees show that in 1919 the costs per hectare were, for the peach trees 1998.55 *lire* plus sinking fund, at 6 %, for 15 years, 194.12 *lire*; and for the walnut-trees, 39 in number, 510 lire plus sinking-fund at 6 %, for 100 years, 27.95 lire.

In reckoning the average expenses of the peach tree the life of the tree is divided into 3 periods: — (*a*) Unproductive (1st-3rd year); (*b*) maximum productivity (4th-9th year); (*c*) period of decline (10th-15th year).; For the walnut there are 2 periods: — (*a*) Unproductive (1st-8th year); *b*) minimum productivity (9th-16th year).

During the first period of the peach, the average is cost 1350.92 lire per annum plus amortisation at 6 % for 12 years (life of peach tree). 151.30 *lire*. During the second period the cost is 3958.12 *lire* and during the third 3067.17 *lire* per annum.

The yield from the peach during its period of maximum productivity averages 200 quintals of peaches a year, which at 50 lire per quintal gives a gross return of 10 000 *lire* and therefore a net profit of 10 000 - 3958.12, or 6041.88 *lire* per annum.

During the period of decline the average crop is 130 quintals giving a gross return of 6500 *lire* and a net profit of 3432.83 *lire* per annum.

---

(1) See *R*, May, 1912, No. 804; *R*, Aug., 1912, No. 1183. (*Ed*)

The total gross profit per year for the 12 years is 4732.85 *lire* which, divided amongst the different factors of production gives: — Labour 26.73 %, accidents and supervision 20.90 %, owners profit 25.80 % and the rest in fertilisers, fungicides, insectides, land rent, extras and guarding, interest on farming capital, amortisation.

The cost of the walnut tree during the first period is 470.85 *lire* plus an amortisation of 72.51 *lire* per annum. During the second period the cost is 744.36 lire.

The output is 2 quintals of nuts worth 400 lire per quintal and the net receipts total 55.64 *lire*. The gross revenue is distributed as follows per annum: 40 % for labour; 12.65 % for amortisation; 12.40 % for fertilisers; 12 % for accidents and supervision, the remainder is absorbed by extras and guarding land, rent, interest on farming capital, and the residue 6.95 % is net profit for the owner.

Both in peach and walnut growing the highest percentages are for labour, accidents supervision and amortisation. The high percentage due to labour indicates that peach cultivation is carried out intensively with a high yield, as is shown by the percentages for accidents and supervision.

The total yearly cost of the three associated herbaceous crops is 2 861.85 *lire* per annum during the life of the peach. All the crops together give a gross return of 8 394.70 *lire* per annum which is distributed as follows: —

	Average yearly expenses	Percentage of the basic elements in relation to gross yield	Proportion of distribution gross yearly receipts divided amongst the various items
	lire		*lire*
Fertilisers	413 33	4.50	525.15
Manual labour	2870.00	34.24	3723.52
Fungicides and insecticides	120.00	1.46	161.70
Contingencies and superintendence	342 60	4.13	444.48
Rent	720.00	8.67	939.82
Interest on capital	127.45	1.52	160.56
Accidents and administration	1407.66	16.88	1857.57
Amortisation	445.58	5.33	572.90
Net profit	1948.08	23.27	
Total	**8394.08**	**100.00**	**8394.70**

This table shows the large reciepts obtained from peach cultivation 1948.08 *lire* per annum of which 1220.35 *lire* is due to the peach. This easily accounts for the extension of peach growing. It is interesting to note that the walnut gives a good yield for a number of years and grows well amongst the most productive herbaceous crops.

95 - **The Cost of Vine and Grapes to the Growers of Asti (Piedmont, Italy)** (1).— DALMASSO, G., in *L'Italia agricola*, Year LVII, No. 9, pp. 267-271. Piacenza, Sept. 15, 1920.

In the following tables the author shows :— (1) The present cost of reconstituting a vineyard attacked with phylloxera, i. e., a specialised crop with American vines ; (2) the cost to the producer per quintal of grapes from this vineyard. The distance between the lines is 1.75 metres, between the vines 1 metre, and there are 5700 vines per hectare.

Cost of making 1 hectare of vineyard.

First Year

	Lire
Digging (0 85 0.70 5 700 m. at 2.25 *lire* per metre)	12 825.00
5 700 grafted rooted plants at 1.20 *lire* each	6 840.00
Planting, 1 man for 15 days at 6 *lire* per day	90.00

Sulphur, 70 kg. at 110 *lire* per 100 kg.	77 00
5 sprayings, 10 days at 15 *lire* per day	150.00
3 sulphurings, 8 days at 7 *lire* par day	56.00
Harvest, 2 men at 15 *lire* + 5 women at 7 *lire* per day	65.00
Piquette: 89 days, 2 litres per day = 178 litres at 100 *lire* per hl	178 00
General costs as in 1st year	180.00
Interest or estimated expenditure 3641.50 *lire* at 6 $^{0}_{0}$	218.00
Total . . .	**3 860.00**

Yield in 3rd Year.

	Lire
Grapes, $^1/_4$ Normal yield, 18 quintals at 125 *lire* per quintal	2 250 00
Shoots, 200 bundles at 0.20 *lire* each	40.00
Total . . .	**2 290.00**

Final cost of the establishment.

First year 30 412 *lire* = 1.06	34 122.15
Second year 1 629 75 *lire* × 1.06	1 727.55
Third year 3 860.00 *lire*	3 860.00
Total . . .	**39.709 70**

The revenue lost from the land during these three years, should be added. Taking the value of a hectare ready to be sown at 15.000 lire at 3.5 $^{0}_{0}$, the profit is 525 lire; the accumulation of this profit for 3 years is therefore :—

$$525 \frac{(1.06)^3 - 1}{0.66} = 1671.40 \textit{ lire.}$$

The establishment cost at the end of the third year is therefore 39 709.70 + 1 671.40 × 41 381.10 *lire*, which after deducting receipts for the third year (2290 *lire*) = 39 091.10 *lire*. Therefore, with 5700 plants per hectare the cost per plant is 6.85 *lire* at the end of the third year.

Cost of amortisation and interest on the establishment cost. — Estimating the life of a vineyard at 35 years (32 plus the first 3 while it is being established) and ther ate of interest at 6 %; the rate of amortisation can therefore be reckoned by applying the following formula: —

$a = Awr \frac{1}{(1 + r)^{n - 1}}$, or $An = 39.091.10$ *lire*, $r = 0.60$ and $n = 32$, so that the rate of amortisation and interest is equal to 2 775.60 lire.

Annual cost of cultivation per hectare of vineyard.

Fertilisers: — Every 2 years, 5 quintals, superphosphate at 25 *lire* per quintal 1.5 quintals potassium carbonate at 55 *lire* per quintal, 1.5 quintal cyanamide at 100 *lire* per quintal, equal. every 2 years to 357.50 *lire*, or annually	178.75
Spreading the fertilisers, 4 days at 6 *lire*	24.00
Renewal of stakes 12 per annum at 6 *lire* each	36 00
Canes and stakes: 4270 canes at 5 *lire* per 100 + 200 stakes at 20 *lire* per 100.	253.50
Staking, 12 days at 6 *lire* per day.	72.00
Dry pruning, 20 days at 6 *lire* per day.	120.00
Gathering and cutting shoots, 5 days at 4 *lire* per day	20.00
2 hoeings, first 30 man days, second 25 man days at 12.50 *lire* per day.	687.50
Green pruning, 30 days at 7 *lire* per day	210.00
Copper sulphate, 75 kg. at 250 *lire* per 100 kg.	187.50
Lime, 75 kg. at 15 *lire* per 100 kg.	11.25
Sulphur: 100 kg. at 110 *lire* per 100 kg.	110.00
5 sprayings, total 13 days at 15 *lire* per day (the first at 12 *lire*)	190.00
3 sulphurwashes, 10 days at 7 *lire* per day	70.00
Thinning out, 10 days, at 7 *lire* per day	70 00
Harvest, 10 days (men) at 14 *lire*, 24 women at 7 *lire* per day.	368.00
Piquette: 114 days at 2 litres per day = 228 litres at 100 *lire* per hl.	228.00
General charges, as in the 3 first years.	180.00
Interest at 7 % for 6 months on general charges 3.100.00 *lire*	108.50
Rate of amortisation and interest on establishment cost	2 775.60
Profit on land investment, 15 000 *lire* at 3.5 %	525.00
Total	**6 509.60**
Subtract the sale of 500 bundles of shoots at 0.20 *lira* per bundle = 100 lire.	
Therefore the total cost of grape production per hectare = *Total*	**6 409.60**

As the vineyards are newly reconstituted with American vine an average crop can be expected of 70 quintals per hectare, which brings the cost of production of 1 quintal of grapes to 91.50 *lire*. Therefore it is desirable to limit vine-growing to those places where the natural, technical and economic conditions are such as will ensure a high, and if possible, constant yield.

PLANT DISEASES

GENERAL INFORMATION

96 – **Royal Decree of November 14, 1920. No. 1751 Regulating the Trade in Plants and Seed within the Kingdom of Italy.** — *Gazzetta Ufficiale del Regno d'Italia*, Year, 1920, No 303, pp. 4004-4005. Rome, December 24, 1920

Art. 1. — Living plants, or portions of such plants, with or without soil, and seeds intended for cultivation or reproduction, no matter of what kind, can be dispatched within the Kingdom by any means of transport, if provided with a permit granted by a delegate of the Ministry of Agriculture.

Art. 2. — The export is authorised from all parts of the Kingdom of living plants of every kind, except vines, coming from communes where phylloxera is known or suspected to exist, without the obligation of anti-phylloxera disinfection, provided the measures prescribed by the law of June 26, 1913, No. 888 (1) are duly carried ont.

Art. 3. — The permit made out in the terms of Art. 1. takes the place of the certificate of origin granted by the Mayor, for the despatch of plants of every kind, including the vine from communes immune from phylloxera. In these cases, no obligation is required as regards the packing.

Art. 4. — The permit granted under Art. 1 shall take the place of the preventive authorisation of the Ministry of Agriculture, and is a guarantee that disinfection has been carried out in the case of vines or portions of vines sent across immune communes from communes where phylloxera is known or suspected to exist, to similar communes. No regulation is established in this case as regards the nature of the packing, provided that it is disinfected at the same time as the vines.

Art. 5. — The provisions of the preceding articles do not apply to plants or seeds of any kind sent for examination to Phytopathological Institutes, Observatories, to Royal Inspectors of plant diseases, or to Laboratories entrusted with seed control.

DISEASES NOT DUE TO PARASITES OR OF UNKNOWN ORIGIN.

98 - **Change-over Tapping as a Means of Control Against Rubber Diseases, especially against Brown Blast.** — See No 54 of this *Review*.

99 - **Mosaic Disease of Maize in Porto Rico, Louisiana and Georgia.** — BRANDES, E. W., (Pathologist of Sugar Plant Investigations, Bureau of Plant Industry, United States of America) in *Journal of Agricultural Research*, Vol. XIX, No. 10, pp 517-521, pl. 2. Washington, D. C., Aug. 10, 1920.

In 1919-1920, the author observed maize affected by a disease similar to the mosaic disease of sugar in a field just west of Peñuelas (Porto Rico), in New Orleans (Louisiana) and near Cairo (Goergia). Others have reported a similar disease in the Hawaiian Islands and in Guam.

All varieties of maize are not affected to the same extent. In Louisiana, the White Creole variety while marked in some individuals was not excessive. The variety U. S. Select No. 182 is very susceptible to " mosaic," but is not especially injured by it. Golden Bantam appears to be immune.

The author is inclined to believe that in the United States no great damage has so far been done. Probably the disease was introduced on sugar cane within comparatively recent years, in which case it may become much more important in the future. Maize is almost invariably used in rotation of sugar cane land, so that no plantation is ever without maize in some of its fields. This means, of course, that the possibility for spread of the disease is greatly increased

In maize as in sugar cane, the most conspicuous symptom of mosaic is the streaked and irregularly mottled appearance of the leaves In maize, however, the lower, older leaves have a greater tendency to resume their normal colour. In the youngest leaves, either the normal dark green or the pallid affected tissue may predominate in a given specimen, but the latter condition is most frequently encountered. In such cases, the areas which remain normal are in the shape of broken or interrupted streaks or lines extending in the general direction of the long axis of the leaf, and the contrast in colour between these areas and the surrounding pallid areas is very decided. In most cases, the mosaic pattern is more prominent at the base of the leaf, where it diverges from the leaf sheath. Where the normal dark green is predominant, the light green affected tissue appears usually as a very fine mottling, or as irregular elongated streaks on the darker background From the foregoing description it can be seen that the patterns vary considerably, and yet they have certain general characteristics which make it almost impossible to confuse this condition with any other affecting the leaves.

Infected plants are always lighter in colour than healthy plants. In some cases, the colour becomes decidedly yellow ; a decided stunting of the whole plant then follows. No case has been observed to terminate fatally, but certainly considerable injury results from the lack of functioning chloroplastids, and where a large percentage of plants are affected, the loss due to decreased size of ears is appreciable.

When infection takes place early in the growing season, partial or complete sterility of the ears results. In some cases, plants affected have resumed their normal colour after several weeks.

Experiments have demonstrated that mosaic disease is dispersed through the medium of *Aphis maydis*, but there is no reason for supposing that transmission in nature is limited to this insect. It is not yet known whether the virus can survive the winter in seed, but experiments are now in progress that may throw some light on this phase of the problem. It has been proved that the virus of maize mosaic is identical with that of sugar and of sorghum, so that even if it is found not to be transmitted by the seed, perpetuation of the disease in the perennial grasses would explain its appearance on maize in the spring.

Control measures for this disease must be based fundamentally on the removal of sources of the infection. So far as is known, the only sources of infection are the living host plants. Destruction of these plants will, therefore, effectively eradicate the disease from any region. From the practical standpoint, the destruction of all affected host plants presents almost unsurmountable obstacles. The substitution of immune varieties of maize as well a sugar cane does not offer any immediate solution, since the most susceptible varieties happen to be the ones the most esteemed.

DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS

100 - **Diminution in Respiratory Activity and in Metabolism Capacity of Wheat Plants attacked by Black Rust (*Puccinia graminis*).** — See No 24 of this *Review*)

101 - **The Over-Wintering of the Melanconia, *Marsonia Juglandis*, on the Branches and Shoots of the Walnut.** — PEYRONEL, B., in *Le Stazioni sperimentali agrarie italiane*, Vol LIII, Parts 4-6, pp 168-171 Modena, 1920

At Riclaretto, in the Waldensian Valleys (Province of Turin), in April, 1917, the author observed, upon the lower branches and shoots of certain walnut trees, concave patches that were nearly round, or more frequently elliptical, being a little elongated in the direction of the axis of the branch on which they were situated. The smallest of these patches were brown, the largest were whitish in the centre and brown round the periphery. Under a lens, minute block dots were seen on these patches; microscopic examination showed these to be the fructifications, in all stages of development, of *Marsonia Juglandis* (Lib.) Sacc., the conidial form of the ascomycete *Gnomomia Juglandis* (D. C.) Trav.

This conidial form is a common parasite of the walnut, but usually does it little injury. The fructifications are often found on the fruits, as well as on the leaves, but very rarely occur on the branches. The tissues beneath the patches are affected by necrosis and are blackened and isolated by a layer of phellosan which continues for some distance, and makes its way toward the surface, beyond the concavity in a zone which, to all appearance, is healthy.

The fungus was in full vigour, and seemed capable of propagating and carrying the disease to other leaves.

There is only one possible explanation of the presence of the patches on these organs at the date mentioned above. During the previous autumn, the tree was severely attacked by *Marsonia*, and the fungus extended from the leaves to the more tender branches, and especially to the young shoots which were not yet lignified. As soon as winter set in, the fungus stopped growing, and its fructifications remained during the cold season at about the same stage of development which they had attained in the autumn.

M. Juglandis is therefore able to over-winter also in the conidial form, at all events on the branches and shoots of the walnut. It would, however, be advisable in cases of severe attack to keep these organs of the tree under observation, and to cut them off as soon as the characteristic fungus patches make their appearance, all the more, seeing they must form excellent centres of infection in the spring, when the frequent rain transports the conidia, depositing them on the young tender leaves

103 – **Resistance of Certain Trees to Diseases and Insect Pests due to Hybridisation.** — See No 40 of this *Review*.

104 – **The Take-all or Foot-rot Disease of Wheat (*Ophiobolus graminis*) in New York State** (1). — KIRBY, R. ., and THOMAS, H. E., in *Science*, new series. Vol LII, No. 1346, pp. 368-369. Lancaster, Pa., Oct. 15, 1920.

Early in July 1920, a at East Rochester, New York, attention was attracted to a small area in a field of soft red winter wheat, where the plants were baldy dwarfed and prematurely dead. In many cases secondary culms had been killed soon after their formation. The roots of the plants were rotted and usually broken near the base of the culm: the lower internodes were dark or entirely blackened and enveloped by a dense sheath-like plate of thick-walled brown mycelium. This plate was formed between the leaf sheath and culm, Perithicia in considerable numbers were found embedded in the leaf sheath and mycelial plate. Microscopic measurements of these and ascospores agree very closely with those given by SACCARDO for *Ophiobolus graminis*.

As soon as the fungus was identified, steps were taken to determine the source of the infection and to completely eradicate the disease from the infected area.

105 – **Gumming Disease (*Bacterium vascularum*) of Sugar Cane in Porto Rico.** — MATZ, J., in *Phytopathology*, Vol. X, No. 9, pp. 429-430, figs. 1. Baltimore, M. D., Sept., 1920.

Gumming disease of sugar cane is known to have occurred in Australia (New South Wales and Queensland), Fiji Islands, Mauritius, Java, Borneo. New Guinea, Brazil, and very likely in Tucuman, Argentina. There is, no record of it in the West Indies. The disease apparently does not occur in India.

---

(1) See also *R.*, April, 1920, No. 470. (*Ed.*)

In February, 1920, gumming of sugar cane was identified by the author in two car loads of cane from the Trujillo Alto district, Porto Rico. The gummy exudation (varying in colour from a lemon-yellow to the colour of honey), at the cut ends of the cane stalk, together with the bright red vascular bundles in the canes in more advanced stages of the disease, are symptoms that agree with the gumming of cane in Australia as described by COBB and studied by E. F. SMITH. Masses of the bacterium in pure culture were smeared on needle-pricked surfaces of leaves of 10 healthy young "Otaheite" canes in an isolated greenhouse. After 3 months from inoculation all these plants showed, when cut, typical gummy exudation from the fibro-vascular bundles.

Immediately upon the recognition of the fact that gumming disease exists unmistakably in Porto Rico, a special survey was made of all the principal sugar cane growing centres, and it was found that the disease is not widespread and the exact locations of its occurrence are only in the Trujillo Alto district in the area of about 15 km. Specimens of the diseased cane were shown to men who have planted cane for many years, but all were unanimous in declaring it a new thing. One planter alone, stated that he had noticed it to a very limited extent the previous year.

The disease occurs in localities where no new introductions of seed have been made for many years past, and it was found in the oldest varieties grown on the island, namely, "Otaheite," "Rayada," "Crystallina" and "Cavengerie" or "Colorada". The Otaheite is the most severely attacked, while the "Cavengerie" is the least attacked. It seems very likely that the disease has been in existance in the island for some time past in insignificant proportions, but the unusually heavy rains at the beginning of 1920 have very probably aided the spread thereof by taking on the form of an epidemic in one district where Otaheite is usually grown. Whether the disease will subside with the advent of the normal rainfall remains to be seen.

The only safe way to check the spread of the disease is through the planting of resistant varieties. The disease has not been observed in the variety "Yellow Caledonia." The fact that "Rayada" is susceptible makes it rather a difficult problem as this variety is largely grown all over the island. "Cavengerie" shows decided resistance but it is not a very desirable variety from the industrial standpoint.

106 - **Diseases and Pests of Hairy Vetch in the United States.** — See No 48 of this *Review*

107 - **Tomato Diseases in Victoria, Australia.** — BRITTLEBANK, C. C., in *The Journal of the Department of Agriculture of Victoria, Australia*, Vol. XVIII, Pt. 7, pp 413-416. Melbourn, July, 1920.

A brief survey of the tomato diseases which occur in Victoria, followed by a description of the control measures employed. The diseases mentioned are:

(1) Bacterial wilt (*Bacillus Solanacearum*).

(2) Irish potato blight (*Phytophthora infestans*) in the drier portions of Victoria this disease has not caused any considerable loss to tomato growers. Besides the potato and the tomato, a native solanum, *Solanum aviculare* has contracted the disease:

(3) Wilt or "sleepy disease" (*Fusarium Lycopersici*) this has not yet caused any marked loss in those districts of the State most suited to tomato culture.

(4) Target spot (*Alternaria Solani*): important.

(5) Root Rot (*Rhizoctonia Solani*): one of the most destructive seed bed troubles and very common round the suburbs of Melbourne.

(6) Damping off disease (*Pythium de Baryanum*).

108 - **Notes on Spotting of Apples in Great Britain** (1). — Horne, A. S., and Horne, E. V. (Dept. of Plant Physiology and Pathology, Imperial College of Science and Tecnology), in *The Gardener's Chronicle*, Vol. LXVIII, 3rd series, No. 1766, pp. 216-217, figs. 4. London, Oct. 30, 1920.

During the past few years reports of "spotting" in apples in England have been frequently notified, and cultivators have made insistent enquiries as to the cause of the trouble and the remedies likely to prove serviceable in mitigating the same.

Several instances are recorded of the sudden appearance and rapid development of spotting in stores, causing disfigurement of the fruit and greatly prejudicing its sale.

In some varieties, the spots remain small, although they are frequently very numerous (as many as 200 have been counted in individual specimens); in others they grow large and the apples affected decay early in the season.

"Spotting" has been reported from the countres of Berkshire, Cambridgeshire, Kent, Middlesex, Oxfordshire, Surrey, Sussex and Worcestershire, and appears to have spread generally throughout the apple growing districts. It is first observable in orchards towards the end of July and in early August. The spots which are round or of a more irregular outline and are sometimes sunken, forming shallow pits, are usually scattered promiscuously over the surface of the apple. In colour they are dark green, rose, purple or brown.

The varieties attacked are numerous, including many of the well known culinary sorts: Lane's Prince Albert, Dumelow's Seedling (Wellington), Pott's Seedling. Newton wonder, Bramley's Seedling, Ecklinville Seedling, and Peasgood's Nonsuch; and many notable dessert sorts, such as Cox's Orange Pippin and Allington Pippin.

The varieties which escape, include the russets: Christmas Pearmain, Worcester Pearmain, the late pippins:— Allen's Everlasting, Fearn's Pippin, etc.; and Barnack Beaty, Gloria Mundi and Belle Dubois.

A species of *Pleospora* (*Pl. pomorum*) (which is capable of ~~acting as~~ a casual organism), has been discovered and isolated from at least 20 varieties of apples. Several varieties developed spotting as a result of artificial inoculations. In at least 3 sorts — Allington Pippin, Rival and Wealthy, rotting ensued which was directly caused by *Pl. pomorum*.

---

(1) See *R.*, Nov.-Dec., 1920, No. 1193. (*Ed.*)

Pl. pomorum is, however, believed to be not the only fungus capable of causing " spotting ". Several other fungi have been isolated, but their rôle has not yet been ascertained. These include *Alternaria Grossulariae* and *A. pomicola*.

Several new fungi have been identified as attacking apples (1) of which the most noteworthy is *Polyopeus purpureus*. This fungus has been obtained from at least 20 sorts of apples, and it is considered probable that it is a casual organism. In addition to this, *Leptosphaeria vagabunda*, prevalent in America on twigs of different trees, and *Coryneum folliicolum* said to cause cankers on twigs and branches of American apples, have been obtained.

From the very frequent occurrence of spots at the lenticels, there is every probability that the infection by fungous organism takes place at the lenticel

As regards control measures the following rules should be observed : —

(1) Winter spraying, preferably towards the end of December with 1 % Burgundy mixture ;

(2) Winter spraying of interplanted trees and bush fruits. It is known that certain fungous organisms spread to the apple from other host plants, *e. g.* the *Alternaria grossulariae* from gooseberries to apples ;

(3) General sanitation : — as the fungi which cause disease in fruit trees are able to exist in dead wood and leaves, decaying fruit, cankered twigs and branches, and in untreated wounds of various kinds.

(4) Summer spraying : — as spotting shows itself first towards the end of July, a single spraying with a one-half per cent. Burgundy mixture, during early July should prove an effective direct method of prevention ;

(5) Insect control : — it is believed that the infection of apples is brought about to a great extent through the agency of mites and other small insects ;

(6) Store sanitation :— the store room should be systematically disinfected and fumigated ;

(7) Since the fungi concerned in " spotting " grow very slowly at low temperatures (0°C to 5°C), some system of cold storage combined with store sanitation is recommended. This is very necessary where apples subject to attack are stored after gathering from trees not previously sprayed.

109 - ***Spirospora Castaneae* n. gen. and n. sp., a Deuteromycete found on Chestnuts in France.** — MANGIN, L. and VINCENS, J, in the *Bulletin trimestriel de la Société mycologique de France*, Vol. XXXVI, Part 2, pp. 89-97, figs. 7 Paris, 1920

The examination of chestnuts attacked by black rot (2) has revealed the presence of other, and rarer, micromycetes, among which is a new genus of Denteromycetes (*Spirospora*), represented by a single species to which the authors have given the name of *Spir. Castaneae.*

---

(1) See *R.* Nov.-Dec. 1929. No. 1193. (*Ed.*)

(2) See *R.*, July Sept., 1919, No. 1042. (*Ed*)

The pulp of the chestnuts was altered and yellow ; part of the surface of the seed-coat beneath the pericarp of the achene, was covered with an efflorescence of a chocolate-brown colour ; this the microscope showed to be wholly composed of large, characteristic multicellular spores.

The authors describe the formation in artificial cultures of these spores and the accessory conidia, as well as that of simple sclerotia or of perithecia, the characters of the mycelium, and the germination of the spores. Finally they give a detailed description of the genus *Spirospora* (which is closely related to the genus *Mycogone*) and of the species *Spir. Castanae.*

110 - ***Phomopsis Pseudotsugae* n. sp., Deuteromycete Parasitic on the Douglas Fir (*Pseudotsuga Douglasii*), in Scotland.** — WILSON, M., in *Transactions of the Royal Scottish Arboricultural Society*, Vol. XXXIV. Pt. 2, pp. 145-149, pl. 2. Edinburgh, 1920.

More than 10 years ago attention was directed in Scotland, to specimens of the Douglas Fir, *Pseudotsuga Douglasii*, from 6-10 years old in which the leading shoot had been killed for a distance of 6-12 inches behind the apex. Examination of the damaged portions led to the belief that the injuries could not be attributed to frost.

Some years later, other similar specimens were collected, and on the dead shoots the fructifications of a species of *Phoma* were noted. During the last 18 months, numerous specimens have been obtained and examination has shown that the disease is undoubtedly caused by a species of *Phomopsis*. The specimens attacked were received from several localities in Perthshire, from near Forres, and from Argyllshire, Dumfries and Inverness, and it may be concluded that the disease is widely spread in Scotland. Trees are attacked up to about 10 years old both in nursery stock and in plantations.

Two types of attack may be distinguished. In the first, the leading shoot (or occasionally a side shoot) is killed back for a variable distance, usually about 9 inches. In the second, the young tree is attacked a short distance above the ground-level, the outer tissues are killed on one side only or completely round the stem, and ultimately the whole tree is destroyed. In both cases, a very characteristic feature of the disease is the sudden decrease in diameter in passing from the healthy to the diseased portion of the stem, and this is very marked in the second method of attack described above, where the stem immediately above the diseased portion is abnormally increased in thickness. Numerous resin blisters are developed on the stem both above and below the point of attack, and after these have burst, the whitish patches of dried resin are very obvious.

Some time after the stem is attacked, minute black fungus fructifications appear in large numbers on the dead portion and in some cases on the dead leaves. These are at first covered, but are later on exposed by the splitting of the bark and finally project slightly above the surface.

They contain very minute spores which, in damp weather exude from the fructifications in mucilaginous filaments or masses of whitish translucent appearance.

The fungus found in Scotland on *Ps. Douglasii* is believed to be a new species and is designated here as *Phomopsis Pseudotsugae.*

A plantation of *Ps. Douglasii* in Perthshire about 6 to 8 years old, was examined in April 1920, and it was estimated that half of the trees had been killed by the disease. The dead trees were removed and burnt and the spaces were replanted with fresh trees. In September about 20 % of the trees were showing signs of attack, and these included some of those planted in the previous April. The method and time of attack are not yet fully known.

Ripe spores capable of germination, have been collected in April and October, and it is probable the infection takes place during the summer. In all probability the species is a wound parasite, this must certainly be the case where the main stem of plants 4 to 8 years old, is directly attacked not much above ground-level, although it is possible that young uninjured shoots may become infected.

The narrowing of the stem in the infected portion is the result of the death of the cambium and consequent stoppage of secondary thickening. Probably some considerable time elapses between infection and death of the cambium. In the case of a tree 6 to 8 years old infected near the base, secondary thickening of the infected portion probably ceases about a year after infection when the leaves begin to turn yellow ; death probably takes place during the following winter. In a tree in which the leading shoot is infected near the apex, growth continues during the following summer and death of the shoot takes place in the winter. Fructifications of the fungus are often found all over the dead trees, and it is evident that the fungus can live on as a saprophyte afterwards.

Owing to the long period which elapses between infection and the first obvious signs of disease, it is possible that the latter may be distributed by the nursery stock which is apparently healthy, although really diseased.

Young plantations should be carefully examined for trees showing early signs of the disease, and these should be removed and burnt.

INJURIOUS INSECTS AND OTHER LOWER ANIMALS

111 - ***Athene brama,* The Spotted Owlet Useful in Agriculture in India.** — FLETCHER, T. B., and INGLIS, C. M., in *The Agricultural Journal of India,* Vol. XV, Pt. 3, pp. 235-238 + 1 pl. Calcutta, May, 1920.

The Spotted Owlet (*Athene brama*) occurs abundantly throughout the Plains of India and Burma, although not found in Ceylon. It is in evidence during the evening and is quite a domestic owl. It is one of the birds that hawks white ants, and is a great bat hunter, but apparently this habit is perhaps local or confined to a few individuals. It lives chiefly on insects and to a less extent on mice, shrews and lizards etc., its insect prey consisting mostly of beetles and crickets. In the case of 8 birds examined at Pusa, of 69 insects taken, one was of a useful species, 26 were neutral and 42 were injurious A case is mentioned, in which a pair of *A. brama* had apparently killed a nesting paroquet (*P. torquatus*), and taken possession of the nest for themselves. As *P. torquatus* is a distinct nuisance to the agriculturist it is wished that *A. brama* would act regularly in this way.

At Pusa, this owlet seems to live chiefly on large crickets (*Brachytrypes* and *Gryllotalpa*) and on dung-beetles. There is no doubt that it is a most useful bird in all districts where large crickets occur so commonly as to do damage. As these crickets are nocturnal, their most effective natural enemies are those, such as *A. brama*, which are also nocturnal.

A. brama breeds from February to April, slightly earlier in the south and later in Northern India, but the greater majority of birds lay in March.

112 - Means Adopted in Crau for the Control of the Moroccan Cricket (*Dociostaurus maroccanus*) in 1920. — VAYSSIÈRE, P., — Communicated by M. LOUIS DOP, Delegate of France.

As the Moroccan cricket (*Dociostaurus maroccanus*), has multiplied to such an alarming extent since 1917 as to threaten the existence, not only of the crops growing in the plain of Crau, but also of those in the neighbouring regions, a systematic campaign was organised in the spring of 1920 with the object of checking the increase of this pest.

The course of the invasion of 1917 to 1920, the work during the previous campaign, and the biological observations made, are the subject of a complete report which will appear subsequently. It, however, seemed desirable to describe the measures adopted for the destruction of the crickets during their various stages, and the results that have been obtained.

The control operations were organised under the direction of a " Defence Syndicate " (Syndicat de défense) which adopted flame-throwers, poisoned baits, chloropicrin solution, and collection on sheets.

The necessary staff for carrying out these measures was furnished by the War Ministry, and the economic importance, of the undertaking being fully recognised, a certain number of soldiers were specially instructed in the use of flame-throwers (Army model P3). Towards the end of May, in spite of difficulties connected with the condition of the country, the XVth C. A. supplied nearly 250 men belonging to the corps and provided with 60 flame-throwers with their accessories (bottles of compressed air, fuses, etc. On the other hand, thanks to the assistance of the Services interested) both military and civil, and especially of the P. L. M. Co. (in transport, it was possible to procure, though sometimes unfortunately, not as soon as was desired, all the products necessary for initiating the campaign.

In order to carry out this task satisfactorily, the military contingent was divided into gangs, each containing from 6 to 10 men. These were distributed in the " Mas," where they were billeted on the agriculturists, who were to recompense them according to the services rendered. As occasion arose, these gangs were transported on motor-lorries (lent by the military authorities) together with all their appliances, which at first consisted of 4 flame-throwers with accessories, 24 bottles of compressed air, 50 fuses, 1 barrel of heavy oil, 100 kg., of bran, 5 kg., arsenious acid, 5 kg., salt, 20 kg., molasses, and 1 sheet for collecting the insects when beaten down.

(1) *Flame-throwers.* — From the experiments carried out in 1919 by M. BAZILE, in which the author also took part, it seemed that the control of crickets should be based upon the rational and systematic use of these implements of war. Details will not be repeated here that have already been published (1), but it suffices to say that the surface cleared by a single charge of a P3 flame-thrower (13 litres) is nearer 500 sq. m., than 200 sq. m., as previously given. Further, the best results were obtained by directing only one or two flame-throwers on the same spot. Experience has indeed shown that 3 operators placed 3 to 4 metres apart in front of a column of crickets hinder one another, and owing to the large amount of smoke liberated, run the risk of seriously injuring their comrades by means of the flame. Also, as a rule the various flame throwers differ in length of flame-jet, combustion of fuse, etc., which entails difference in the progress of the operators.

Excellent results were obtained by the following method:— 4 or 5 men provided with branches or sacking slowly beat down the crickets towards a certain point, in order greatly to increase their concentration at that spot. This operation, if well directed, is easily effected, even in the case of the winged insects. When it is concluded, the beaters retire, and a flame-thrower, after taking in the situation at a glance, can in a few seconds, calmly and quickly (this is soon learnt by practice), sweep all the surface covered by the insects.

Under such conditions, the whole charge can be completely exhausted in two minutes (including loss of time due to change of position by the operator, in order to ensure greater efficacy), and in 15 jets of flame. It is, however, not necessary to empty the flame-thrower at one time. It is indeed indispensable that the operator should stop (for instance, at the word of command), when his work is not needed. Therefore, someone must always be at hand in order when required, to turn off the air-tap, while the operator extinguishes his fuse.

It can easily be understood that in an operation such as just been described, two or three flame-throwers stationed in front of a column of crickets would interfere with one another on changing position, and that it is necessary to reach the insects before they are dispersed by the confusion due to the first flame-jets

The use of several flame-throwers at a time is, however, not to be rejected, especially in combating columns of young crickets often only

---

(1) See *R.* July-Sept. 1919, No. 1049; *R.* Jan. 1920, No. 147. (*Ed*)

4 to 6 m. wide, but extending for several hundred metres. Then, two flame-throwers with similar appliances, if placed in front, and advancing at the same pace for 20 metres, can obtain excellent results.

Finally it may be said that the use of single or massed flame-throwers is a question that must be decided at the time, and it is only possible to make some suggestions on the subject.

(2) *Poisoned baits.* – This control method was first applied in the case of irrigated crops, and was subsequently extended as circumstances required to all ground invaded by crickets. As time was then devoted entirely to practical work, not to experiment, no attempt was made to find new poisoned bait formulae, but use was made of those already studied in 1919, and of which the mode of use has been given in a preceding Report (1).

Owing to the excessive cost of oranges and lemons, at the end of a few days, these fruits had to be omitted from the arsenical mixture which, however, did not seem to detract in any way from its efficacy. The following is the recipe handed to all the gangs entrusted with the preparation of the paste:

I.	Bran	10 to 12	kg.
	Salt	0.500	»
	Arsenious acid	0.500	»

Mix these three substances very thoroughly before adding the solution, which should have been previously made up.

II.	Water	2	litres
	Molasses	2	»

Mix again very thoroughly, so that all the bran is completely impregnated with the liquid. Should the mixture be too dry, add a little water (one or two litres at most).

The bait should not be prepared save at moment of using it (at night fall, or before in the morning). Spread the bran broad-cast over the irrigated crops. Take all precautions necessary in handling very poisonous substances such as washing the hands well after the operation. A mask should be used when making mixture I.

The bait was spread before the insects become active in the morning, or else at night fall. The results seem to be the same in either case. They one indispensable condition for obtaining a good bait, however, is that the various ingredients should be as thoroughly mixed as possible. In this case it was mixed by hand, especially as any given gang seldom prepared more than 100 kg., of poisoned bait a day. In places however, such as Africa, where the swarms of locusts are larger, but less numerous, it would be advisable to have special mixing-machines, such as ratus devised by G. PAOLI in Italy (1). Use could also be made of a barrel turning on a horizontal axis, such as was recommended for the preparation of poisoned grain in the control of field mice in the liberated regions (1).

---

(1) Cf. P. VAYSSIÈRE, Les sauterelles dans le Sud-Est de la France en 1918, *Ann. Serv. Epiph.*, VI, p. 289. Paris, 1919.

The amount of bran spread per hectare was variable, but an average of 30 to 60 kg., according to the size of the column, is about right.

The toxic action of the mixture is shown even the next day, when already some dead insects are seen, whilst many more are unable to fly and drag themselves along or lie on one side. The excrement is blackish and liquid. The maximum mortality appears to occur on the third day, but not infrequently the bait retains its toxic properties for a fortnight. The insects collect at the foot of plants, or to be more exact, most of them are found beneath the trees or plants upon which they have passed the night. According to the few calculations effected, the average number of dead crickets per 59 metres was about 600. In certain cases, however, only 200 could be counted, although in others, the number was 1000 or more, which would mean some 10 000 000 insects per hectare. This remedy is obviously most efficacious, and should be used in France against pests like grasshoppers.

(3) *Chloropicrin solutions.* — As excellent results had been obtained with these during the experiments made in 1919, it was hoped that they could be used on a large scale in combating crickets. Unhappily, owing to circumstances over which the author had no control, he was unable to obtain the necessary products at the right time, or to use them under the best conditions. However, 500 kg., of chloropicrin was employed in a soap solution which gave most satisfactory results in the proportions by weight of 2 parts of coconut oil soap ; 10 of chloropicrin : 100 of water.

(4) *Collecting the crickets on a sheet.* — This method was chiefly used when it was urgently necessary to meet the difficulties due to want of labour and especially of heavy tar oil which, on account of the strikes, was no longer supplied us by the factories. By the use of collecting sheets, 2000 to 5000 crickets were collected daily in the whole of Crau during one month. The insects thus captured were in the 4th and 5th stages.

To sum up, the use of the control methods described made it possible considerably to minimise the bad effects of the abnormal multiplication of the Moroccan cricket in Crau during the spring of 1920. The efforts of the Defence Syndicate were all the more praiseworthy sceeing that, at certain moments the success of the campaign against the crickets was extremely problematic, owing to numerous difficulties of a general character

114 - **Destruction of Termites by Means of Chloropicrin** (1). — FEYTAUD J., in the *Comptes rendus hebdomadaires des seances de l'Académie des Sciences*, 1920, Second Half-Year, Vol CXLXI, No 8 (August, 23, 1920), pp 440-442 Paris, 1920

Laboratory experiments made by treating with chloropicrin vapour fragments of infected pine-tree trunks placed under large bell-jars have proved that chloropicrin vapour is very effective against *Leucotermes lucifugus* Rossi. At a temperature of 20° C., 2 mgm, of chloropicrin per litre was sufficient, with 12 hour's exposure, and 5 mgm., with 6 hours, to destroy all the termites, both those set free within the bell-glass, and any living at a depth of 10 cm. in the pieces of wood

The effect of the chloropicrin upon the termites is first shown by the insects becoming restless and agitated; they crowd towards the interior of the galleries, which explains the accumulation of dead and dying ants and the confusion reigning in these passages. Then there supervenes a condition of paralysis that passes quickly into death, if the action of the vapour be continued for some hours, though otherwise it may last for several days, but in no case do the ants recover.

In order to destroy a colony of *L. lucifugus*, it is thus not necessary to kill all the individuals by the treatment, provided they are all paralysed Nevertheless, with a view to being more certain of the effect produced, and to overcoming the difficulty of penetrating into the wood which increases in proportion to the thickness of the latter, the author tried, as far as possible, to give the doses and exposure that caused the instantaneous death of the insects under the bell-jar. Thus, in his experiments on trunks covered with tarpaulin, and on pieces of beams in a small room. he took as his basis the minimum exposure of 12 hours in an atmosphere containing 10 mgm., of chloropicrin per litre; under these conditions, the results were excellent.

The practical application of his method in a villa at Saint-Jean-de-Luz (Basses Pyrénées), consisting of a ground-floor, and two other storeys, confirmed the results of the experiments made in the laboratory.

We have therefore every reason to hope for excellent results in the use of chloropicrin for the disinfection of houses infested by termites. If applied with the necessary precautions, and in the manner adapted to each case this process has shown itself to be easy and free from all risk.

115 - **Disinfection of Cotton Seed by Means of Dry Heat.** — SCHRIBAUX, E., in *L'Agronomie Coloniale*, Year V, No 34, pp 103-104 Rochefort-Paris, October, 1920

In the course of experiments undertaken for the purpose of determining the action of dry heat in freeing cotton-seeds from animal parasites, two different lots of the seed of this Malvaceae were subjected to rising temperatures of 60° C, 65° C., 70° C. and 75° C. for one two, and three hours.

It was shown by these experiments that, up to 70° C., the vitality of the seeds treated for a time varying from one to three hours was in no-wise impaired; at 75° C, the seeds nearly all died after two hour's treatment, or else produced yellow, sickly seedlings According to the author, a temperature of 60° C. is enough to destroy all the animal parasites of the cotton plant.

---

(1) See also *R.*, June, 1920. No. 705 (*Ed*)

Given the small amount of cotton seed used per hectare, it is not necessary to employ a costly apparatus, all that is required is to mix the seeds with very fine dry sand, or sawdust, previously heated in a large caldron to the temperature of 60° C. A few preliminary experiments will show how much must be used under the given conditions so that the mass can be kept at 60° C. for at least one or two hours.

GENERAL INFORMATION

118 - **The Natural Control of Anopheles Larvae by Means of Aquatic Insects.**— FEDERICI, E, in *Atti della R. Accademia dei Lincei, Serie Quinta, Rendiconti, Classe di Scienze fisiche, matematiche e naturali*, Vol XXIX, Parts 3-6, pp. 170-173, Parts 7-8, pp. 224-247, Second Half year. Rome, 1920.

The larval forms of Libellulidae and Dityscidae, as well as certain adult Coleoptera and Rhynchots, which are known to be very voracious and to prey upon other aquatic insects, have been suggested, in a general way, as probable destroyers of anopheles. The author has tested this assertion by the help of laboratory experiments, using different groups of the insects representing the fresh-water entomofauna of Italy, and anopheles during the larval and adult stages. He discovered the following facts.

Anopheles larvae are very well protected by their peculiar conditions of life, and especially by the fact that they nearly always assume a horizontal position on the surface of the water and in the immediate neighbourhood of floating plants. This greatly reduces the number of predatory insects that may be regarded as more or less contributing to the destruction of the anopheles. Of these predatory insects, those that wage most successful war against the pests are: among the rhynchota, the genera *Naucoris, Notonecta, Corisa* (larvae and adults), either on account of their relatively large size, or because of their number and voracity; among the Pseudoneuroptera, the larvae of the genera *Aeschna, Anax, Calopteryx, Gomphus, Agrion, Lestes* and other similar insects, but these are less formidable foes and probably only destroy the anopheles larvae in shallow ponds, where, these is a large amount of submerged vegetation at a short distance from the surface.

The destructive effect of these predatory insects seems to be of little actual practical importance.

119 - **Importance of Lupins as a Food.** — I. Baut Lupinen ! in *Deutsche Landw. Presse*, No 18, p 140. Berlin, 1920 — II KONIGSDORF, F , Zur Verwertung der Lupinen zu tierischer und menschlicher Ernahrung, *Ibid.*, Nos. 24-25, p. 187. — III. GERLACH and LUECKE, Vergleichende Versuche uber die Entbitterung der Lupinen in Grossbetrieb (Mitteilung des Vereins zur Hebung des Lupinenbaues), in the *Illustrierte Landw. Zeitung*, Nos. 101-102, pp. 437-438, 1920 — IV. MULLER and PRIESHOF (Direktor und Tierzucht-Inspektor, Ruhlsdorf, Kreis Teltow), Erfahrungen mit Lupinenfütterung an Schweinen, in the *Deutsche Landw Presse*, No 96, pp 654-655, 1920.

I. — LUPIN CULTIVATION. — Baron VON WANGENHEIM, president of the " Verein zur Hebung des Lupinbaues " (Association for promoting lupin cultivation in Germany), has started an active propaganda on the dangers of the want of cultivation through lack of fertilisers and proper attention. The first advice that he gives concerning uncultivation and increased food production is to cultivate seed lupins, especially where the cultivation of summer cereals and hoed crops is impossible. The ancient Romans knew how to attenuate the bitter taste of lupins and make them into a food in common use.

The difficult food situation in Germany and the disastrous change it has undergone are sufficient reasons for advising the extension of lupin cultivation.

II. — USE OF LUPINS AS FOOD FOR ANIMALS AND HUMAN BEINGS. — According to M. H. VON FEHRENTEIL, 3 kg. of crushed lupin is equal as regards food value to 10 kg. of oats. In Germany there are 12 million Morgen (3 063 600 hectares) of sandy soil until now untouched which could grow lupins for seed, followed by barley or potatoes; estimating the average yield at 350 kg. per morgen (1332 kg. per hectare), 120 million quintals equivalents to oats could be obtained.

Lupins deprived of their bitter taste and mixed with potatoes and dried carrots, form an excellent food for animals. The water in which the lupins are soaked to remove the taste makes a better fertiliser than night-soil. Dough making, fermenting and cooking tests of flours containing 10-20 % of lupin flour have given satisfactory results.

III. — COMPARATIVE TESTS OF METHODS OF REMOVING THE BITTER TASTE FROM LUPINS ON A LARGE SCALE. — During the summer of 1920 the authors carried out numerous experiments on this subject at the Janikow starch-factory, in Pomerania, at the request of the " Association for encouraging lupin cultivation ".

Four industrial methods were tried. — That of KELLNER-LÖHNERT using boiling water ; that of BACKHAUS (patented), using potash lye ; that of BERGELL (also patented), using common salt ; that of THOMS, using hydrochloric acid. The lupins were mixed (yellow and blue species) and were partly mouldy and damp. The whole mass (1000 quintals) was dried at once and 250 quintals taken for the tests (25 quintals per test).

In the first series of experiments, the best results were given by the THOMS process, with which the residual content of alkaloids of the de-bittered lupins when dried was 0.029 %, whereas with the other three processes it was more, being 0.1 %, which was taken as the maximum limit of tolerance.

The operation was improved during a second series of experiments, however, and the lupins sweetened and dried to the same degree had the following percentage composition:

Composetion	Original lupines bitter	Sweetened lupines			
		KELLNER-LÖHNERT	BERGELL	THOMS	BACKHAUS
	%	%	%	%	%
Moisture	13 19	10.00	10 00	10.00	10.00
Crude protein	41.76	42.82	38.64	41.40	42.62
Crude fats extracts	4.92	4.05	3.17	3 54	3.16
N., free extracts	22.41	23.38	25.72	24.85	24.53
Cellulose	13.47	16.36	17 67	17.79	15.54
Ash	4.25	3.39	4 80	2.42	4.15
	100.00	100.00	100.00	100 00	100.00
Pure albumin	37.86	41.87	36.75	40.01	41.65
Non digestible albumin	2.14	7.52	8.13	8 80	5.90
Alkaloids	0.779	0.110	0.045	0.039	0.065

It follows, therefore that the process least suited for bittering lupins on a large scale is the KELLNER-LÖHNERT (1); but the authors do not doubt that a more prolonged treatment with lye will produce the desired sweetness. Two facts merit special attention with regard to these processes:— The loss of 17 % (BACKHAUS) to 22 % (BERGELL) of dry matter in the sweetened lupins, compared with untreated lupins; and the decreased digestibility of the albuminoids. The first disadvantage is inevitable, but the second can be attenuated by modifying the method of drying the sweetened lupins; the authors intend to deal with this question elsewhere.

In spite of these losses, lupins constitute an excellent food for man and beast, the economic value, however, is governed by the price of the bitter lupins, which depends entirely on the extent over which they are cultivated.

IV. — Hitherto lupin seed has been little used as food for pigs; few experiments have been made and the information is very vague concerning the rations and the production of meat.

At the pig-breeding Station at Ruhlsdorf, the authors carried out feeding trials for 4 weeks with pigs of all ages fed on lupins.

The fattening ration was potatoes, lupins, and salt. On October 6, 1920, a group of 8 pigs, 8 months old, and weighing 60 kg. each, was made. For some time before the experiment, those animals that were accustomed to pasturage, received a supplement of lupins which they accepted immediately.

---

(1) M. KELLNER recommends the boiling-water process as more simple and preferable. *Cfr.* O. KELLNER, *Die Ernährung der landw. Nutztiere.* Parey, Berlin, 1916, p. 278. (*Ed.*).

The lupins of the yellow variety were softened for 12 hours in hot water in a special steamer, then steamed for 1 hour and then washed for 24 hours in several changes of water

Reduced to a fine paste the sweetened lupins were mixed with potatoes that had also been steamed; the cold mixture was given to the pigs *ad lib.*

During the experiment the daily consumption averaged 13.4 kg. per head, *i. e.*, 11.23 kg. potatoes and 2.17 kg. soaked lupins, corresponding to 806 gm. of sweet air-dried lupins (humidity 14 %). The average increase in live weight per day per head was 916 gm., so that the production of 1 kg. of live weight corresponded to 0.879 kg. of sweetened, air-dried lupins and 12 kg. of potatoes.

The extraordinarily favorable result of the first period of the experiment (the authors have begun a second one on fattening), suggests that the pigs can be fed on further quantities of this mixture until fat with advantageous results and without danger to their health.

120 – **The Globulin of the Cohune Nut** ***Attalea Cohune.*** — JOHNS, C. O and GERSDORFF, C. E. F. (Protein Investigation Laboratory, Bureau of Chemistry, United States Department of Agriculture Washington), in *The Journal of Biological Chemistry*, Vol XLV, No. 1, pp. 57-67 Tables 12, Pl 1, bibliogr of 12 works. Baltimore, M D December, 1920.

This nut was not commercially exploited until the war, when the shells were carbonised and used in gas masks, the kernels being pressed for their oil, which is of a very high quality and is similar to coconut oil. Experiments are now in progress in British Honduras, (the cohune palm is indigenous to this country) to produce the oil on a commercial scale. The press cake will be suitable for use in feeds.

An analysis of the isolated protein shows that the protein contains all the basic amino-acids necessary to produce normal growth, and gives also a strong qualitative test for tryptophane. The principal protein extracted by means of sodium chloride solution is a globulin This was obtained by dialysing the saline extracts and also by precipitation from the extracts by means of ammonium sulphate. The analyses of the globulin reveals a close similarity between it and the coconut globulin The basic amino-acids were determined by the VAN SLYKE method, and the distribution of the nitrogen calculated from the results (HAUSMANN's modified method).

The free amino nitrogen has also been determined, and has been found to agree fairly well with ½ the lysine nitrogen as determined by the VAN SLYKE method.

The authors state that they were unable to fix on a decisive separation point in the globulin construction, and are inclined to believe that only one globulin is present in the cohune nut.

CROPS AND CULTIVATION

121 – **Agricultural Climatology in Swanland, Australia, and its Effects on the Forest Tracts** — GRIFFITH, TAYLOR, in *Quarterly Journal of the Royal Meteorological Society*, Vol. XLVI, No. 196, pp. 352-364. London, Oct 1920.

The Swanland region designates the south-west corner of Australia. The total rainfall always exceeds 10 inches and it differs climatically in this respect from the rest of Australia except perhaps Eyre Peninsula (S. A.). Few regions in the world exhibit such complete rainfall controls as regards natural vegetation as Swanland. The isohyets run parallel to the coastbounding L-shaped strips, and it is possible to divide the country up into districts having a distinct flora.

From Perth round Cape Leenwin to Albany is a strip 40 miles wide receiving more than 30 in., of rain per annum. This was clothed with splendid eucalypt trees of 3 species " Tuart " (*E. gomphocephala*) in the north, " Jarrah " (*E. marginata*) in the centre and " Karri " (*E. diversicolor*) in the south.

The next strip (from 30 to 25 in.,) is marked botanically by a continuous belt of *E. marginata* and the next (25 to 20 in.,) still further east, by a belt of " Wandoo " (*E. redunca*). In strip 4 (20 to 15 in) is the habitat of the York gum (*E. loxophleba*), and also specimens of Mallet gum Salmon gum (*E salmoniphloia*) and Gimlet gum (*E. salubris*) invaluable for mining timbers. These latter grow throughout the drier portions of Swanland *E. diversicolor* and *E. gomphocephala* furnish, on the other hand, excellent timber greatly used for wood-blocks, piles etc.

The appended table shows concisely how man has adapted these belts to his needs.

Rainfall	Timber	Crop	Towns and Mean Monthly Temperature
Over 30 in . . . . . Warmer moiety	*E. gomphocephala.*	Dairies . . . . . Vines. . . . . . Oranges. . . . . Sheep.	Perth . . . . Pinjarra. . . (Jan. 74°, July 55°)
Over 30 in. . . . . . . Cooler moiety	*E. marginata.* . . *E. diversicola* . .	Dairies . . . . . Apples . . . . . Sheep.	Bunbury. . . Denmark . . Albany . . . (Jan. 66°, July 53°)
30–20 in.	*E. marginata* . .	Vines. . . . . . Farms	Gingin. (lately opened up in the South — data insufficient).
20–15 in.	*E. redunca* . . . *E. loxophleba* . .	Great Wheat Belt	Moora. . . . Northam. . . (Jan. 72°, July 50°) York . . . . (Jan. 77°, July 50°) Narrogin. . .
15–12 in.	*E. loxophleba* . .	Dry Wheat Belt. Sheep	Kellerbewin: (Jan. 77°, July 50°)
12–8 in.	Mallet gum. . . Gimlet gum . . Salmon gum . .	Few Sheep and Cattle	Carnarvon: (80°, 61°) Valgoo . . . . Southern Cross (77°, 51°) Kalgoorlie . .

Wheat is by far the most important crop (78 %) and is progressing very rapidly in Swanland, for it has quadrupled its production from 1911 to 1916. Certain varieties are grown in localities with an annual average rainfall as low as 12 in.; these localities occasionally have less than 10 in., in one year and yet may grow wheat fairly successfully with efficient fallowing. There is little grown west of the 30 inch isohyet.

The best areas seem to be those receiving from 15 to 20 in. in the cooler months (April to October).

As regards the less important products, apples grow splendidly in the Karri region, while orchards are general in the Yarrah belt. The vine country lies between the wheat belt and the orchard belt.

122 - **Agricultural Climatology in Tasmania.** — GRIFFITH TAYLOR, in *Quarterly Journal of the Royal Meteorological Society*, Vol XLVI, No 196, pp 354-355 London, Oct. 1920.

Tasmania lies 150 miles to the south of Victoria, between latitudes 40° and 44° S, and its climatic controls differ considerably from those of the mainland. It lies almost permanently under the influence of Antarctic low pressure systems, so that it is swept continuously by the Westerly winds blowing along their northern limbs. Hence the high western region of the island is very wet. A strip about 40 miles long, including Mt. Lyell receives over 100 inches a year which renders agricultural projects impossible. The population is confined almost to the north and east, the chief economic centres being Launceston (January 64°, July 44°) and Hobart (January 62°, July 45°). The tract from Wynyard to Launceston is one of the most fertile and populous districts in Tasmania

In spite of the small size of the island (less than 1 % of the Commonwealth), in such crops as oats and potatoes it is close to Victoria, while a much larger proportion of the population is engaged in orchards and hops than in any of the other States.

Oats is the chief crop, (reaching 2 million bushels in 1916), and the chief centres of production are along the north coast, which received from 40 to 50 inches of rain yearly. This is also grown in the eastern portion of the State, especially near Oatlands (20 to 30 inches).

Wheat is apparently diminishing. Longford is perhaps the chief centre (20 to 30 inches).

The fruits grown in Tasmania include all those of temperate climates but the two out-standing crops are apples and raspberries. The chief centre for both is around Hobart. Potatoes constitute a very important crop on the wet north coast, especially the western half from Wynyard to Sheffield.

Timber is of considerable importance: eucalypts are prevalent in the east (comparatively dry); and in the west (wherever the rain exceeds 50 inches), the eucalypt is largely replaced by the evergreen beech (*Fagus Cunninghami*).

123 - **Mathematical Enquiry into the Effect of Weather on Maize Yield in the United States.** — WALLACE, H A, in *Monthly Weather Review*, Vol 48, No 8, pp 439-446. Washington, August, 1920.

Mathematical studies undertaken with a view to the determination by means of the correlation coefficient method the relationship between various weather factors, (rainfall and temperature in the months of May, June, July and August) and the maize yield.

The method of calculation is by means of correlation coefficients, multiple coefficients of correlation, and lines of regression.

TEMPERATURES AND RAINFALL OF SUMMER MONTHS — The average temperatures for the 29-year period for the 8 maize-belt States are as follows :—

TABLE I. — *Average temperature* 1891-1919.

States	May	June	July	August
	°F	°F	°F	°F
Iowa	59.8	69.2	74.0	72.0
Illinois	62.5	71.6	75.8	74.2
Indiana.	62.4	71.3	75.3	73.6
Kansas	63.7	73.4	78.1	77.5
Minnesota.	54.8	64.7	69.5	67.1
Missouri.	64.9	73.4	77.3	76.3
Nebraska	58.9	68.9	74.3	72.8
Ohio	60.6	69.3	73.7	71.8

TABLE II. — *Average precipitation* 1891-1919.

States	May	June	July	August
	Inches	*Inches*	*Inches*	*Inches*
Iowa	4.66	4.40	3.85	3.40
Illinois	4.22	3.84	3.49	3.32
Indiana.	4.10	3.87	3.48	3.29
Kansas	4.67	4.63	3.73	3.32
Minnesota	3.51	4.17	3.63	3.40
Missouri.	4.99	4.78	4.08	4.08
Nebraska	3.48	3.81	3.24	2.83
Ohio	3.73	3.79	3.94	3.27

In Ohio, the July rainfall is unquestionably the dominating weather factor. The temperature in May, however, is also important, the correlation coefficient being + 0.325, which is relatively high. In some states west of Ohio, the temperature during July assumes an even ~~more~~ dominant position than the rainfall. In Illinois there is a correlation between temperature and yield of —0.657, whereas between July rainfall and yield the coefficient is + 0.651 ; the yield is therefore much higher when it is wet and cool in July.

TABLE III. — *Correlation coefficients between maize, yield and weather.*

States	Yield and temperature				Yield and rainfall			
	May	June	July	August	May	June	July	August
Indiana	+ 0.200	— 0.115	— 0.474	+ 0.040	+ 0.072	+ 0.083	+ 0.591	+ 0.423
Illinois	+ 0.222	— 0.322	— 0.637	— 0.144	+ 0.096	+ 0.110	+ 0.651	+ 0.330
Iowa	+ 0.153	— 0.100	— 0.294	— 0.020	— 0.056	+ 0.117	+ 0.122	+ 0.273
Kansas	— 0.060	— 0.477	— 0.748	— 0.555	+ 0.463	+ 0.410	+ 0.770	+ 0.540
Minnesota	+ 0.224	+ 0.380	— 0.077	+ 0.400	+ 0.041	0.000	+ 0.131	+ 0.422
Missouri	— 0.027	— 0.565	— 0.654	— 0.541	+ 0.263	+ 0.337	+ 0.534	+ 0.495
Nebraska	— 0.110	— 0.217	— 0.594	— 0.424	+ 0.432	+ 0.276	+ 0.587	+ 0.382
Ohio	+ 0.325	— 0.098	— 0.172	— 0.086	— 0.308	+ 0.132	+ 0.653	+ 0.350
Floyd County (Iowa)	+ 0.320	+ 0.220	— 0.096	+ 0.170	+ 0.101	+ 0.083	+ 0.085	+ 0.188
Polk County (Iowa)	+ 0.085	— 0.382	— 0.510	— 0.240	—	—	+ 0.180	+ 0.492

In Missouri, the correlation is — 0.651 with temperature and only + 534 with rainfall: July temperature obviously has more effect than rainfall

In Iowa and Minnesota, the correlation coefficient between yield and July rainfall means practically nothing.

In Iowa the coefficients are as a general rule, very low; the strongest is the negative relationship between July temperature and yield(— 0.294).

For the other States, the observations are as follows: in Indiana, the most important weather factor is the July temperature with a correlation coefficient of — 0.474, July rainfall + 0.591 and August rainfall + 0.423. In the case of Illinois, the July temperature and rainfall and May temperature are involved.

MULTIPLE CORRELATION COEFFICIENTS. — The author has calculated the multiple coefficient of correlation between the yield on the one hand and the 3 selected weather factors. This formula applied in the special case under discussion can be stated thus: —

States	Weather combination	Correlation coefficient
Missouri	June temperature; July temperature; August temperature	0.79
Iowa	May temperature; July temperature; August rains	0.464
Iowa, Polk County	June temperature; July temperature; August rains	0.62
Iowa, Floyd County	May temperature; June temperature; August rains	0.405
Nebraska	May rains; July temperature; July rains	0.67
Indiana	July temperature; July rains; August rains	0.66
Minnesota	June temperature; August temperature; August rains	0.56
Ohio	May temperature; July temperature; July rains	0.746
Illinois	May temperature; July temperature; July rains	0.81
Kansas	June rains; July rains; August rains	0.862

Taking into account all the weather factors as a whole instead of considering one only, it may be noted from this table that the correlation coefficients are very marked and distinctly high.

LINES OF REGRESSION — There is a positive correlation coefficient, as for example between the yield and the rains, an increase in the latter will correspond to an increase in yield. By means of the formula for working out lines of regression, it is possible to calculate the increase in yield relative to the meteorological value.

The average June temperature for Missouri is 73.4° F., that for July, 77.3° F., and for August 76.3° F. As the present time the normal maize yield is 28.1 bushels per acre.

Between the yield of maize and June temperature, the correlation coefficient is negative. Applying the formula for working out the line of regression the author found that for each extra degree June temperature is above 73.4° F corresponds to a decrease in yield of 0.8 bushels, whereas for each degree below 73.4° F, the maize yield is increased by 0.8 bushels.

In a similar way, in July and August, a rise or fall of 1° F, córresponds to a decrease or increase in yield, equal to 1.1 and 0.4 bushels respectively for each decree.

Taking a specific case; when in Missouri, the June temperature is 72.4° F, the July temperature 75.3° F and the August temperature 75.3° F, we should expect a yield 0.8 bushels above normal, because of the low June temperature, 2.2 bushels above normal because of the low July temperature, and 0 4 bushels above normal because of the August temperature or a total of 3.4 bushels above normal, or a yield of 31.5 bushels per acre.

In Missouri, between the yield of grain and the temperature in June, July, and August, there is a rather high multiple coefficient of correlation of 0.79.

PREDICTING FORMULAE FOR MAIZE YIELDS. — By means of working out the lines of regression, the predicting formulae can be taken as fairly accurate. The following have been worked ont by the author:

Iowa: $x_0 = 0.77\, x_1 - 1.4\, x_2 + 1\ 26\, x_3.$

where x_0 = % deviation of yield.
x_1 = deviation of May temperature from average in °F.
x_3 = deviation of July temperature from average in °F.
x_8 = deviation of August rain from average, in inches.

Illinois:

$x_0 = 0.98\, x_1 + 4.33\, x_2 + 4.38\, x_3.$
where x_0 = % deviation in yield.
x_1 = deviation of May temperature from average in °F.
x_2 = deviation of July temperature from average in °F.
x_3 = deviation of July rain from average in inches.

Ohio:

$x_0 = 0.8\ x_1 + 1.9\ x_2 + 0.9\ x_3$.
where x_0 = % deviation of yield.
x_1 = deviation of May temperature from average in °F.
x_2 = deviation of July rain from average in inches.
x_3 = deviation of August rain from average in inches.

Kansas:

$x_0 = 3.7\ x_1 + 10.7\ x_2 + 7.5\ x_3$.
where x_0 = % deviation of yield.
x_1 = deviation of June rain from average in inches.
x_2 = deviation of July rain from average in inches.
x_3 = deviation of August rain from average in inches.

Minnesota:

$x_0 = 1.6\ x_1 + 0.8\ x_2 + 4.2\ x_3$.
where x_0 = % deviation of yield.
x_1 = deviation of June temperature from average in degrees.
x_2 = deviation of August temperature from average in degrees.
x_3 = deviation of August rain from average in inches.

Floyd County, Iowa:

$x_0 = 1.65\ x_1 + 1.14\ x_2 + 1.83\ x_3$.
where x_0 = % deviation in yield.
x_1 = deviation of May temperature from average in degrees.
x_2 = deviation of June temperature from average in degrees.
x_3 = deviation of August rain from average in inches.

Polk County, Iowa:

$x_0 = 0.8\ x_1 - 2.4\ x_2 + 3.1\ x_3$
where x_0 = % deviation
x_1 = deviation of June temperature from average in °F.
x_2 = deviation of July temperature from average in °F.
x_3 = deviation of August rain from average in inches.

Indiana:

$x_0 = 1.6\ x_1 + 3.6\ x_2 + 1.5\ x_3$.
where x_0 = % deviation of yield.
x_1 = deviation of July temperature from average in degrees.
x_2 = deviation of July rain from average in inches.
x_3 = deviation of August rain from average in inches.

Nebraska:

$x_0 = 3.48\ x_1 - 2.96\ x_2 + 3.08\ x_3$.
where x_0 = % deviation of yield.
x_1 = deviation of May rain from average in inches.
x_2 = deviation of July temperature from average in °F.
x_3 = deviation of July temperature from average in inches.

In applying these formulae, it is possible to predict more or less exactly the yield under consideration.

IOWA WEATHER AND YIELD OF MAIZE. — The multiple coefficient of correlation between yield and May temperature and August rain is disappointingly low, and the method of correlation coefficients is not well adapted in this case, considering that Iowa is probably the most important of all the maize States.

A superficial examination of the evidence leads to the conclusion that the low correlation coefficient in Iowa is due to the fact that there are some seasons and some sections in which the yield is low because of the particularly cool weather during the greater part of the summer, whereas in other years the yield is low because of the hot weather.

It is generally recognised that in exceedingly hot seasons, the yield is often excellent in northern Iowa, whereas in Southern Iowa the yield will be very seriously damaged, and vice versa in cool seasons. The existence of these contrasts can only lessen the value of the correlation coefficient. It is considered advisable therefore to confine attention to less extended areas, in order to mitigate the above mentioned contrasts.

Taking Polk County (S. Iowa) and Floyd County (N. Iowa), it will be noticed that the relationship between temperature and yield was as follows: May temperature + 0.085; June temperature — 0.382; July temperature — 0.510; August temperature — 0.240; July rainfall + 0.180; August rainfall 0.492. The three most important factors are apparently June and July temperatures and August rainfall. The multiple coefficient of correlation is 0.62; this is somewhat higher than that secured for the entire State. On the other hand, as it has already been shown, the higher the multiple coefficient, the more exact are the lines of regression and the prediction relative to the yield.

A series of 8 tables includes all the data relative to the increase or decrease of yield in relation to the rise and fall of meteorological values: the use of these tables permits the formation of predictions concerning the yield to be very nearly accurate.

In Floyd County which is situated only 150 miles north of Polk the following are the correlation coefficients. May temperature + 0.32; June temperature + 0.22; July temperature — 0.10; August temperature + 0.17; July rainfall + 0.083. Warm Mays are apparently of distinct importance in Floyd County, and whilst the warm Junes and Augusts tend to produce on the average a positive effect, it is precisely the contrary in the case of Polk County.

The lines of regression calculated for Floyd County are utilisable from a practical standpoint when the season maintains a distinct type throughout such as 1915, which was cool and wet, and consequently injurious to the crop. The decrease in yield corresponds very nearly to that predicted according to the correlation coefficient.

On the contrary, in 1912, May and July were warm, whereas June and August were cool. The rainfall was practically normal throughout the season. The yield, which according to the calculated coefficients should have been only slightly higher than the normal yield, showed a superiority of 42 %.

CONCLUSIONS. — The problem of predicting the maize yield from the weather is relatively simple in the southern half of the "corn belt," notably in Kansas, Missouri, and Southern Illinois, where drought and heat in June, July, August are the chief influences. The problem is to measure the degree of drought and heat with accuracy. In the northern part of the "corn belt" and especially in Northern Iowa, the application of the proposed method has not given practical results. The relationship between the yield and the July temperature, for example, is not strictly linear. For instance, when the July temperature is 68° F, the yield may possible tend to increase 6 % above normal; when 69°, to 13 %; when 70° to 14 %; when 71° to 15 %; when 72° to 13° (already a less marked degree of increase in yield with a temperature above 71°); when 73°, 12 %; when 74°, 10 %; when 75°,8 %; when 76°, 6 %; when 77°, 4 %; when 78°, 2 %, and finally, temperatures above 78° produce a diminution below the normal mean; when 79°, this has already amounted to 2 %.

In any case, the correlation formulae may be applied in a general way for trial purposes and taken as a whole, to weather conditions relative to different crops.

124 - **Damage to Crops by Weather in the United States.** — WARREN SMITH J, in *Monthly Weather Review*, Vol. 47, No. 8, p. 446. Washington, Aug. 1920.

The following table gives the average damage per cent. to crops in the United States due to different factors or unfavourable weather conditions:

	Deficient Moisture	Excessive Moisture	Floods	Frost or Cold	Hail	Hot winds	Storms	Total weather	Plant diseases	Insect pests	Animal pests	Defective seed	
Wheat	12.4	2.0	0.3	4.5	1.1	2.0	0.3	22.9	2.7	2.1	0.2	0.2	28.8
Maize	16.3	4.0	0.9	2.0	0.4	2.2	0.5	27.7		2.7	0.2	0.7	32.1
Oats	13.4	2.7	0.3	0.8	0.8	1.9	0.4	20.8	1.7	0.9	0.1	0.2	24.5
Barley	17.1	1.8	0.1	0.8	1.3	3.2	0.4	24.9	1.7	0.7	0.3	0.1	28.7

125 - **Frost and the Prevention of Damage by It.** — *Farmer's Bulletin* No. 1096. United States Department of Agriculture, pp. 3-48 Figs 24. Washington D. C. April 1920.

A description of the actual effect of frost on soil and vegetation, followed by a discussion of various methods and devices now being used for protection purposes, and the temperatures injurious to plants, blossoms and fruits, with special reference to citrus fruits.

126 - **The Choice and Use of Instruments for Measuring Radiation in Agricultural Climatological Researches.** — VALLOT, J., in th *Comptes rendus de l'Académie des Sciences*, Vol. 170, No. 12, pp. 720-722. Paris, March, 1920.

The amount of solar heat has hitherto only been studied from the purely physical standpoint. It is true that pyrheliometers or actinometers have been made for the purpose of measuring solar radiation, by separating it from sky radiation, but the readings given by these instruments are of a very relative nature, and cannot be reduced to any absolute physical unit.

If it be remembered that the heat supplied by the sky can amount to $^1/_3$ of the direct solar radiation, it is easy to understand how inadequate are these actinometers in researches on agricultural climatology. Of all the existing instruments, BELLANI's totalising actinometer with a blue thermometric basin is the one that has given the best results. It consists of a receptacle of coloured glass containing alcohol, and protected by an exhausted glass sleeve. Acted on by the radiation, the alcohol distills off and condenses in a graduated tube attached to the basin.

This actinometer is checked by comparison with an ARAGO actinometer, both instruments being exposed to the total radiation.

By means of a continuous series of observations, an adjustment curve for the different parts of the condensation tube has been made. When the instrument has been tested and marked, it needs no further checking. By means of careful study, the following facts have been determined:—

(1) The amount of alcohol distilled, decreases as the basin is emptied. The control curve must thus be determined by careful reference to an ARAGO actinometer, or some other previously tested totaliser.

(2) Every instrument has its special curve which is related to the tint of the basin, and the amount of alcohol; when, however, this curve is well defined, it changes no further.

(3) The temperature of the air has no effect upon the distillation of the instrument.

Two readings a day, one taken at mid-day, and the other in the evening, are all that is needed to obtain the total number of calories supplied during the day by the sun and the sky. Therefore, this instrument is perfectly adapted to agricultural meteorological research.

127 – **Experiments on Soil Evaporation in Germany.**— KRUGER, E., in the *Internationale Mitteilungen fur Bodenkunde*, Vol X, Parts 1 and 2, pp. 1-13. Berlin, 1920.

The influence that the nature of the soil exercises on the evaporation of rain water or that which already exists in it, constitutes an extremely important agricultural question. This question has already been the subject of various researches by WOLLNY, FLEISCHER and SEYFERT, and although these workers, have arrived at very different numerical results, they all came to the same conclusion, viz., that a layer of sand spread over peaty soil decreases evaporation.

The author carried out some experiments with peat and mineral soils, with which he filled 6 cylinders made of white metal, with wire-gauze bottoms covered with filter paper, which was saturated with water by capillary attraction by immersion in water, or by artificial rain; afterwards they were exposed to evaporation in a closed place, or one where the air had free access but always protected from the rain.

A series of experiments were made from April 24, 1918 to September,

1919. The loss of water by evaporation determined by means of weighing periodically with due care, are summarised in various tables, from which the author concludes as follows: —

(1) Without rain, the evaporation of peat soil covered with sand (5 cm. deep) is less than that of uncovered peat soil, and the difference is not so great as that recorded by FLEISCHER and SEYFERT (1).

(2) Variations in the depth of the bed of sand have but little influence on the amount of evaporation.

(3) In the presence of rain, these results are inverted, in the sense that, if an area of peat soils is covered with sand, evaporation is greater than if the peat soil is uncovered, with a difference which increases with the frequency, and decreases with the number of times rain falls.

The author also describes other experiments made between March 20, 1917, to January 1918, with a view to contributing to the controversy which exists between soil chemists, some maintaining that the evaporation of clay soils is greater, and others that it is less, than that of sandy soils.

The author has obtained results in the way described above which he has summarised in various tables, from which it appears that:

(4) Without rain, the quantity of water evaporated from clay, with regard to the total humidity of the saturated soil, is less than that of sand.

(5) In the presence of rain, very damp clay soil evaporates much more water, in the absolute sense as well as relatively to the preexisting humidity, that is to say contrary to the results obtained with pure sand (2).

128 – **Cause of Lime-Induced Chlorosis and Availability of Iron in the Soil.** — GILE, P. L. and CARRERO, J O (Porto Rico Agricultural Experimental Station), in the *Journal of Agricultural Research*, Vol. XX, No. 1, pp. 33-61, Tables 13, Pl. 2. Bibliogr of 45 works. Washington, D. C., Oct. 1, 1920

The more important facts already established concerning the causes of lime-induced chlorosis are given together with a full report of certain experiments on this subject, hitherto unpublished.

As a result of soil surveys, several species of cultivated plants showed that a particular type of chlorosis affecting these plants occurred only on calcareous soils. All calcareous soils, however, did not induce chlorosis in these plants, for example, green cane was found growing on a soil containing 76.70 % calcium carbonate. This supports the idea that it is not the carbonate of lime itself that induces chlorosis, but some condition usually associated with the presence of the carbonate of lime.

The weight of the evidence from ash analyses of chlorotic plants seemed to point to a deficiency of iron in the ash as being one cause of chlorosis with possibly an excess of lime as a contributory cause. Previous work with rice showed that the percentage of iron in the ash diminished very markedly as the plants became more mature (1).

---

(1) The action of a covering of sand on the evaporation on the covered soil is also a function of the thermal relation between the covering and the soil. See *R.*, 1916, No. 8 (*Ed.*)

(2) See *R*, 1915, No. 248, and *R.* 1917, Nos. 119 and 704. (*Ed.*)

Treatment of chlorotic plants with iron showed that the lack of iron in the plant was at least one of the causes. Whether the lack of iron is due to a low availability of iron in the soil or to reactions in the plant rendering ineffective the iron absorbed; whether an increased absorption of lime is a contributory cause or whether the reaction of the soil has any effect on the appearance of chlorosis, apart from affecting the iron supply, are all points not proved by these results.

Experiments with various plants showed there is no evidence of a general " lime effect " in inducing chlorosis, the different lime compounds having a varying effect on the plants. Rice, which is sensitive to lime did not appear to be sensitive to the alkalinity except as this alkalinity influences the availability of iron. It was found that the ratio of root to top growth was much increased in calcareous soils and solutions (2). Other work with rice in water cultures seemed to show definitely that the alkalinity of carbonate of lime is not directly injurious to this calcifugous plant, nor is the alkalinity in itself the cause of chlorosis.

The authors' experimental results where a la ge amount of sodium bicarbonate was required to depress growth, seemed to indicate that a slight alkalinity of carbonate of lime could not be directly injurious to rice and this supports the afore-mentioned conclusions.

An attempt was made to demonstrate directly that the only action of carbonate of lime in inducing chlorosis lies in depressing the availability of iron. The principle which tended to make the results less striking than had been anticipated is the following: Plants apparently are unable to attain a maximum absorption of any one element with only a part of their roots (3).

The work on the availability of iron compounds was based on the assumption that the chlorosis and the poor growth of rice in the calcareous soils were caused by a lack of available iron. Previous experiments by the authors proved that colloidal iron was unavailable for rice in water culture (4) and RUPRECHT proved that acid soils may contain much more soluble iron and aluminium than neutral or calcareous soils, even to an injurious extent (5). In the case in hand bulky organic compounds such as stable manure, velvet bean plants and tobacco stems, when used in considerable quantity, however, enabled the plant to secure more iron. The availability of iron in calcareous soils appeared to be slightly greater near the optimum water content of the soil than at higher percentage of water. Although rice becomes chlorotic in calcareous soils with ordinary percentage of water, it may be expected to make a practically normal growth in certain cases of the soils are submerged. This is considered to be due to growth of a new kind of root that is better able to assimilate iron.

129 – **Lime and American Vines** (1) — DE ANGELIS D'OSSAT, G, in the *Atti della R Accademia dei Lincei, Serie Quinta, Rendiconti, Classe di Scienze fisiche, matematiche e naturali*, Vol. XXIX, Parts 1-2, 2nd Half-year, pp. 58-62. Rome, 1920.

Certain authors maintain that it is the quantity of lime which directly causes chlorosis of the plants, and especially of the American varieties; on the other hand, others hold that it is due to the special physical state of the lime rather than its abundance. Amongst the latter are MM. HOUDAILLE and SÉMICHON (1892-1900) who have invented some ingenious instruments for the determination of the specific speed of attack or the chlorotic power of lime contained in agricultural soils.

In Italy, when reconstituting the vines that were destroyed by phylloxera, the degrees of resistance to lime (RAVAZ-GUILLON-BONNET) of the American varieties were followed, and many failures ensued.

TH. SCHLOESING (1872) has shown that the quantity of lime cannot be the only direct cause of chlorosis; he formulated a law in which the tension x of the carbon dioxide of the soil atmosphere is correlated with the weight y of calcium carbonate in solution, expressed by the formula:—

$$x^{0.3787} = 9218\, y.$$

In a previous note (1914), the author proposed to show that the specific speed of attack of the lime, although it existed theoretically, could not yet be determined with sufficient precision. He was able to deduce from his experiments that:— 1) The quantity of calcium carbonate dissolved in a given time is different in limestones of approximately equal, physical state; 2) the quantity of carbonate dissolved in a given time varies also in the same rock; 3) in each lime stone, with the same area and in equal time, repeated experiments have shown that there is an irregular decrease in the amount of substance dissolved.

It is therefore impossible, *a fortiori*, to succeed in investigating the specific speed of attack of the lime which forms part of agricultural soils; the differentiation of this lime under active and passive forms is purely empirical.

In a later note (1920), the author has been able to formulate, using these facts as a basis, a direct contradiction to the scale of resistance. He now makes the following observations on this questions:—

The water circulating in agricultural soils, liberates the bases by its hydrolysing power, and these bases, uniting with the carbonic acid, form the carbonates. Thus the carbonic acid destroys the momentary equilibrium due to the hydrolysis and enables other mineral substances to pass into solution. But the action of the calcium is antagonistic to that of the magnesium, whence the necessity of a ratio between these two elements, which varies for each plant; the most favourable ratio between these two elements for the American varieties is not yet known. Moreover there is an indirect action of this ratio which aids the absorbtion of other nutritive elements. The normal growth of the plant requires physiologically balanced doses of the assimilable elements. Recent experiments have shown that the two elements calcium and magnesium are united to two others, phosphorus and potassium, by well defined influences and relations, and that their action depends on the presence of other mineral elements. The destructive action of an element, however, does not depend on its absolute quantity, but on the degree to which it is absorbed; from this point of view, research, pure and simple, on the quantity of lime in useless.

---

(1) See *R.*, July-Aug., 1920, No 765 (*Ed.*)

The solubility or insolubility of iron and of manganese in agricultural soils is thus united, with the chloroses which it causes, to conditions which do not require a determined quantity of lime, but only its presence or absence in an alkaline medium. But the root acids (oxy-acids) often intervene opportunely; as they form special complex compounds they make the solubility of the iron and manganese equally possible and thus remove an immediate cause of chlorosis. It must be concluded from this that it is the presence and not the quantity of lime which is necessary and that chlorosis is eventually subordinated to the free alkalinity of the soils and to the lack of the emission of certain root acids.

The solution of lime is subordinated, according to the law of SCHLOESING, to the formation and circulation of carbon dioxide in the agricultural soil. Now, the production produced and circulation of this gas depends on the physical properties of the soil; and these depend, in turn, directly on the form in which the colloids occur. It is easy to understand that the action of the carbon dioxide will be favoured in open, porous and permeable soils, whose structure is glomerulate (reversible hydrosols and hydrogels or tending to reverse). Although the calcium plays a certain part in the transformation of the gels into elements which are more or less reversible, it seems evident, however, that the "pedetic" and "antipedetic" phenoma do not depend on the quantity of lime but on the form in which the colloids occur in the soil, that is to say, the presence of the OH-ion in alkaline soils or the *H*-ion in acid soils, and, to a lesser degree, on the monovalence or polyvalence of the radical ions

It cannot be claimed that it is possible to ascertain, by a single volumetric analysis of the quantity of lime contained in an agricultural soil, all the details of so exceedingly complicated a question.

130 - **The Ehrenberg Law on the Relation Between Potash and Lime.** — MAYER, A., in the *Deutsche landwirtschaftliche Presse*, Year 47, No. 14, p 108. Berlin, 1920.

The law in question is formulated by PAUL EHRENBERG as follows: Every time that the amount of lime available is increased for a plant which has but little potash at its disposal, the absorption of potash decreases, with consequences that may be very harmful. But if the supply of potash is increased unilaterally, the plant will be newly safeguarded against the excess of lime and will attain perfect development.

According to the author, EHRENBERG's law can be amply substantiated, and it clears up facts which until now have remained unexplained. All the harmful effects of lime are thus connected with a lack of absorbtion of potash; the apparent calciphobia of lupins and numerous other herbaceous and arborescent plants can be clearly explained by this law.

Nevertheless, the author considers that it not a case of a law of a special kind, but of the consequence of the general law of absorbtion, which is based, not on mysterious selective powers, but on determined physical laws regarding osmosis, as well as on determined physiological laws regarding the fixation of substances which are absorbed in a form which is no longer diffusible. In fact, if several salts are awaiting entrance into the roots, each stands less chance of being absorbed in considerable quantities. The excess of another base in addition to lime, will thus influence the reduction of the absorbtion of potash.

It is necessary to consider, besides, the two independant properties which most crops possess, viz., those of a greater or less need of lime and potash and of a greater or less aptitude for appropriating them at the expense of substances of varying assimilability. As regards this, the author suggests that special tables should be drawn up to show these two properties in different plants, which would be of practical use for fertilisers and crop rotations

The author states that the direction followed by agricultural chemists who wish to confine metabolism to the narrow limits of physical and mathematical knowledge is entirely erroneous.

131 – **Effect of Alfalfa on the Subsequent Yields of Irrigated Field Crops.**— SCOFIELD, C S., in *United States Department of Agriculture, Bulletin*, No 881, pp 1-13, Tables 5 Washington D C, August 10, 1920.

Report of experiments carried out at 3 different Stations in the northern Great Plains, to ascertain the extent of the beneficial effect of growing alfalfa in rotation with Irish potatoes, oats and sugar beets grown on irrigated land. The trial tests covered a period of 6 years. Comparison is also made between these crop yields when grown in the same sequence but without alfalfa. A further comparison is made in the case of potatoes and sugar beets, as to the relative effect of alfalfa in rotation and the application of farmyard manure at the rate of 12 tons per acre, once during the period of rotation.

Results showed that when the soil is a light sandy loam, the effect of alfalfa has been to increase the yields per acre as follows:— potatoes about 100 bushels, oats about 6 bushels, sugar beets 3 4 tons:

On heavy clay loam rich in organic matter, no beneficial effect was apparent, and the effect on oats and sugar beets was too slight to be regarded as significant.

On a very productive clay loam, the increase in yields per acre showed: — for potatoes; about 50 bushels, without, however, increasing the proportion of marketable potatoes, which was relatively high on all the plots, oats about 11 bushels, and sugar beets about 1.5 tons.

While these results do not show a strikingly beneficial effect from the use of alfalfa in the rotation in the case of oat yields, it should be noted that these crops were grown on soil that was virgin at the beginning of the experiment and of relatively high productivity as shown by the mean yields of all the plants included in the experiment. In the case of sugar beets the alfalfa appeared nearly as beneficial as the periodical applications of manure, even although the position of the beet crop in the alfalfa rotation was not so favourable as in the manured rotation. While both manure and alfalfa have increased the yield, the size of the beet, and the vigour of growth as expressed in the larger proportion of tops, there has not been a corresponding increase in the percentage of sugar in the beets.

132 — **Fertilising Value of Water Used to Remove the Bitter Taste of Lupins.** — See. No 119 of this *Review*

133 - **Studies on Alpine Plants.** — BERTIN, L. (Fellow of Paris University), in *La Nature*, No 2435, pp. 353-356, figs 4. Paris, Dec 4, 1920

Alpine plants are characterisd by :— The limited development of the epigeal parts in contrast to the enormous development of the hypogeal parts; great hairiness; large, brightly coloured flowers, that are very nectariferous; rich aroma; thick cuticle which protects the leaves; distribution of the chloroplasts throughout the whole mass of leaves instead of their being localised towards the upper surface as is the case with the plain species; epidermis of the stem thickened and suberified, or furnished with some other protective tissue, etc. These plants therefore have been considered quite different from their relations of the plains.

But, as the result of experiments extending over 35 years and still in progress, M. G. BONNIER, Professor of Botany at the Sorbonne, has succeeded in transforming meadow species into alpine species. He has made use of three methods, viz.: (1) Comparative cultivation in plain and mountain; (2) cultivation in an artificial " Alpine environment "; (3) cultivation in seed-plots.

(1) The same plant gathered from the plains was divided into several cuttings, of which some were cultivated and multiplied in the plains and others on the mountains. Of these last, a large part perished from the effect of cold without snow; others became transformed very quickly, but died some years later. On the other hand, about sixty species adapted themselves to the new environment and became transformed into alpine species. There were thus obtained from the same initial plant always reproduced agamously: — *Trifolium pratense* of the plains and *T. nivale* of the mountains; and respectively *Juniperus communis* and *J. nana*; the common cistus and the helianthemum cistus of the Alps; *Veronica officinalis* and *V. Tournefortii*, etc.

(2) The alpine climate is specially characterised by very warm days (up to 50° C.), by cold nights, by intense light, and by a short period of growth.

By covering with pounded ice, from September to June, the soil of the pots in which the experiments were made; by putting the pots every night, from July to August, into a refrigerator and exposing them during the day to the warmth of the solar rays further increased by reflecting mirrors, M. BONNIER has reproduced artificially, at the Biological Station of Fontainebleau, the chief conditions of the alpine climate except that of altitude. The meadow plants cultivated under such conditions, agamous reproduction always being used, were not long in changing their form; the epigeal part diminished greatly, the leaves became a darker green, the flowers more brightly coloured, etc. In short they were transformed, so to speak, into "artificial Alpine plants".

(3) In July, 1919, M. BONNIER sowed at the Pic du Midi (altitude over 6000 ft.), seeds of various species gathered from the plains; the plants obtained resembled not the meadow species, but the corresponding alpine species. Thus from seeds of the *Trifolium pratense* he obtained plants equal to *T. alpinum* plants of the same age. The same thing occurs with wild poppy, cornflower, mallow, lucerne, columbine, and burdock.

134 - **Researches upon the "Flowerless" Apple-tree.** — LONGO, B, in the *Atti della R. Accademia dei Lincei, Serie Quinta, Rendiconti, Classe di Scienze fisiche, matematiche e naturali*, Vol. XXIX, Part 9, pp. 290-291. Rome, Nov. 7, 1920.

From a superficial examination it would appear that the so-called "flowerless apple-tree" bears fruit without having flowered. But, in reality, the plant produces small floral buds, of which some open, some only partly open and other do not open at all. However, even those which open do not produce visible flowers, for their petals are very small (smaller than the sepals) and sepaloid. The flowers are pistilliferous but show no trace of stamens; in the place which the stamens occupy in the common apple-tree are found several free pistils. Consequently each flower is composed, not only of the five adherent carpellary leaves, which form the usual lower pentalocular ovary, but also by several other carpellary leaves, situated higher up and each forming a pistil.

Thus the carpellaries, and consequently the cells, are arranged on two levels; on the lower level are the 5 adherent leaves, as in the common apple-tree. On the upper level are the others, free, which are not found in other apple-trees.

In the above-mentioned flowers there is no pollinisation, because they are not visited by honey-seeking insects. Despite this, both the flowers which open and those which remain shut bear fruit which, however, does not contain seeds. We are confronted then with a true parthenocarpy in the strict sense of the word, since the plant bears fruit without seeds and without its having been fertilised or pollenised.

Microscopic examination shows that each of the cells on the lower level contains 2 more or less normal ovules. Those of the upper level either contain none at all, as is most frequently the case, — or contain only one or very rarely two; but generally these ovules are abortive and in very few cases attain completely normal development.

The author has tried artificial pollinisation, making use of the pollen of other sorts of apple-trees, and has obtained fruit with seeds which he proposes to sow in order to continue his studies.

135 - **Composition of Brazilian Maniocs.** — See No 155 of this *Review.*

136 - **Tannic Substances in the Mulberry.**— GHIRLANDA, G, in the *Atti della R Accademia dei Lincei, Serie quinta, Rendiconti Classe di Scienze fisiche, matematiche e naturali,* Vol XXIX, Part 4, pp 146-148 Rome, Feb 15, 1920

Researches undertaken at the " R. Stazione bacologica," at Padua, show that, except the wood of the branches, all the parts of the mulberry contain appreciable amounts of tannic substances. The leaves contain the most (0.509 % of the dry matter collected in the morning, 0.417 % in the evening) ; followed by the root bark (0.36 %) branch bark (0.209 %) and root wood (0.119 %). The quantity of tannin in leaves collected in the morning is greater than that in leaves collected in the evening, contrary to what has been observed for the organic substances. This may be explained by the hypothesis put forward by several authors, viz., that the tannic substances are not produced by assimilation, but may well be secondary products of the synthesis of the albuminoids.

137 - **Influence of Low Temperatures on the Germination of Wheat as soon as Harvested and on Fresh Seed in General.** — MUNERATI, O, in the *Atti della R. Accademia dei Lincei, Serie Quinta, Rendiconti, Classe di Scienze fisiche, matematiche e naturali,* Vol. XXIX, 2nd Half-year, Parts 7-8, pp 273-275 Rome, 1920.

The author has studied the mechanism of the quiescence (resting) of the seeds of some of the worst weeds of the Lower Po Valley, in the hope of being able to apply the results of his studies. His attention was drawn to the question by a communication from G. T. HARRINGTON published in *Science* (New Series, Vol. L, No. 1301, p. 428) in which this author affirms, contrary to the general opinion, that 100 % of ordinary cereals can germinate as soon as harvested, provided that they are maintained at a temperature of 12-16° C. The author has observed the same phenomenon with wheat gathered in different localities, during harvest and immediately after threshing. The tests were made simultaneously in an incubator at 33-35° C., at a laboratory temperature of 25-28° C., and in a refrigerator. The average results were as follows :—

	Percentage of grain germinated	
	after 3 days	On the 12th day
At 32-35° C.	3	14
» 25-27° C.	14	29
» 12-15° C.	81	96

Wheat seed of the 1919 crop under the same conditions gave, after 12 days, about 55 % in the incubator, 84 % at normal temperature, and 93 % in the refrigerator.

Further experiments also show that a sudden drop in temperature due to storms, results in greater germination than in the case of grain tested on the same day in a common medium, and that these same samples, tested at another period with a normal temperature gave a much smaller rate of germination.

The author also wished to ascertain whether low temperatures could cause quicker germination of the so-called "fresh" seed, belonging to common weeds. The largest seed of *Avena fatua* (which is the first of the seeds of that species to emerge from the quiescent stage), was put to germinate a week after harvest: it gave on the 12th day: —

At a temperature of 25—28°..... 3 % germination
» » » » 12—15°..... 72 % »

A. fatua seeds usually germinate in great numbers in the autumn after they have fallen on the soil. This is not due solely to the great amount of rain which falls when this grain is undergoing those intimate changes that "perfect" them or make them "ready for germination," but also to the low autumn temperatures. These observations, whilst confirming G. T. HARRINGTON'S observations on this subject, show the necessity of modifying the fundamental ideas prevalent as regards the interpretation of the mechanism of quiescence of certain types of seed. HARRINGTON'S and the author's researches do not confirm the supposition that the embryo of these seeds is not "physiologically perfect" at harvest time, or lacking diastases that can make the reserves available.

138 - Respective Roles played by the Bases, Potash, Lime and Magnesium, in Cultivated Plants. — LAGATU, H., in the *Comptes rendus de l'Académie des Sciences*, Vol. CLXXII, No. 2, pp. 129-131 + 1 fig. Paris, Jan. 10, 1921.

The recent development of the use of and trade in magnesium as a fertiliser, particularly in the form of calcined dolomite, is worth the attention of agricultural scientists. The works of LOEW and many cultural tests show that the addition of magnesia and lime to the soil may, in certain cases, be more advantageous than lime alone. The author has investigated the question for which plants the analysis of the crop suggests this practice more specially.

Among the mineral nutrients that plants absorb he reckons potash, lime, and magnesia. He admits that each of these bases plays a specific part, in other words that they cannot replace one another, and so he has adopted the common monobasic equivalent $\frac{K_2O}{2}, \frac{CaO}{2}, \frac{MgO}{2}$, that is to say, the quantity of base necessary to neutralise an acid equivalent, such as 46.5 of hydrochloric acid.

On the other hand the requirements of the crop as regards these three bases is known. The percentage of potash, lime, and magnesia contained in different plants can be used to calculate the basic equivalents, and the following problem arises :— Out of 100 basic equivalents attributed to the whole of the potash, lime and magnesia basis, what part does each play in the various crops ?

The author, using the analytical statistics given by MUNTZ and A. CH. GIRARD in their classical work *Les engrais*, has drawn up a table, of which the following is a part :—

	Potash Per cent.	Lime Per cent.	Magnesium Per cent.
Wheat	43.4	28 3	28.3
Maize.	49.1	23.9	27.0
Sugar beet	42.1	24.0	34.8
Lucerne.	21.2	67.4	11.4

The various crops show very different distributions of the 100 basic equivalents. A better method of comparison would be to make a graph of the equivalents, using the result from each crop as a point. The graph could be made on the surface of an equilateral triangle or a rectangular isosceles triangle. This last method is shown in the figure on page 164.

Interesting agricultural and physiological observations are suggested by this graph. In order to use magnesia correctly as a fertiliser the median of the right-angle is used. This corresponds to the ratio :

$$R = \frac{\text{number of magnesia equivalents}}{\text{number of lime equivalents}} = 1$$

This ratio has been the object of important studies by LOEW and his associates. The analytical statistics shown by the graph indicate that amongst the cultivated plants, the sugar beet above all, then mangolds, maize, and potato correspond to a ratio of $R < 1$. In other words, these plants require a greater chemical action from magnesia than from lime.

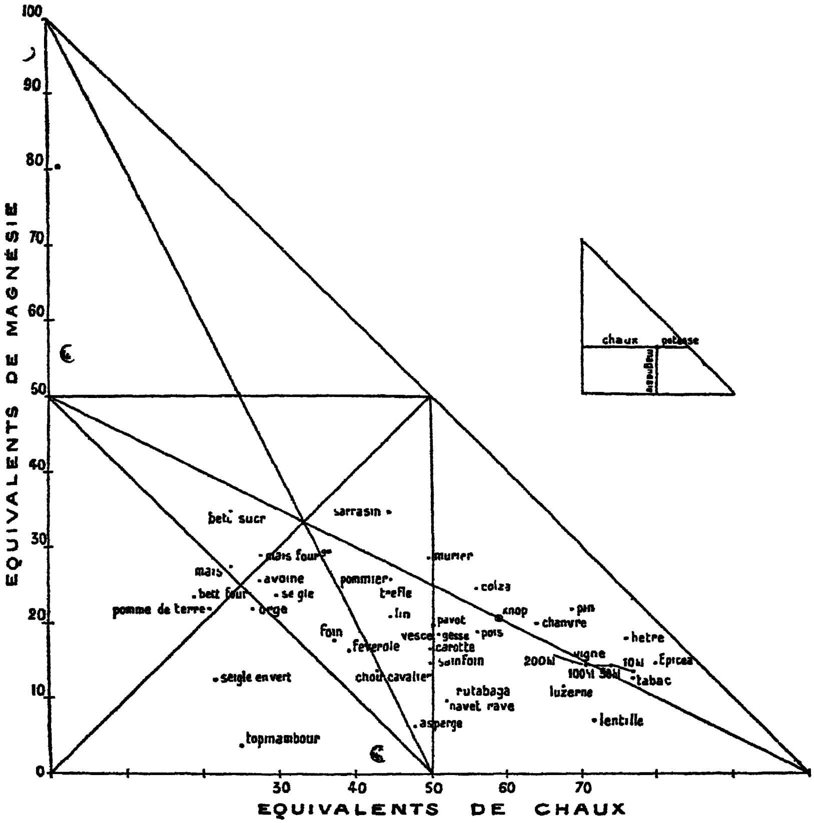
Wheat requires exactly the same amount from each of these 2 bases ; oats, rye, barley, and buck wheat approximately the same. These analytical deductions explain the experimental results recently obtained with calcined dolomite, more particularly with reference to the plants cited above. On the other hand, it does not appear justifiable to expect all cultivated plants to give the same order of results.

The median lines and those parallel to the sides of the triangle delimit the most interesting areas :

(1) The small rectangular-triangles having a common apex with the main triangle : if the representative point is found in it, one of the bases represents an alkalinity greater than that of the sum of the two other bases.

(2) A quadrilateral, being the height of the mid points of the two sides of the main triangle, and a corner coinciding with an apex of the triangle if the representative points is situated in it, one of the bases represents an alkalinity greater that that of each of the bases, considered separately.

[138]



Equivalents de Magnesie = Equivalents of magnesia.
Equivalents de Chaux = Equivalents of lime.
Asperge = Asparagus
Avoine = Oats
Bett. fourr. = Mangold
Bett. sucr. = Sugar beet
Carotte = Carrot
Chanvre = Hemp
Chou cavalier = "Cavalier" Cabbage.
Colza = Rape

Trèfle = Clover
Vesce gesse = Spring vetch
Vigne = Vine

[138]

139 - **Method for Measuring the Transpiration of Living Plants.** — FREEMAN, G. F. in *The Botanical Gazette*, Vol. LXX, No. 3, pp. 190-216, figs. C 5, Tables 6. Chicago, Sept. 1920.

As the result of studies extending over several years, considerable experimental data have been accumulated concerning the transpiration of alfalfa and other plants under various accurately measured conditions of temperature, relative humidity and wind movement.

These data are however very general and it was impossible to say whether a given result was simply the product of the physical factors then prevailing or to what extent it was modified by the physiological reactions of the plant itself. It should be considered possible to calculate from rational formulae the behaviour of a physical evaporating surface for the given conditions. Any departure from the result could then be attributed to the response of the living organism.

The general type of such a formula should remain always the same, but the constants will vary with all the changing conditions of environment, temperature, wind movement, relative humidity etc. The purely physical experiments here reported were designed, first to work out the generalised type of the formula, and then to obtain the constants for certain special cases of environment and other factors.

INSTRUMENTS AND METHOD EMPLOYED. — The evaporating surface used was a porous cup atmometer inclosed in a glass cylinder of 1 litre capacity. A constant stream of air was drawn through the cylinder (over the atmometer) by a rotary air pump. Then the air was measured by a water gasometer which was accurate to 1/1000 of a cub. ft. The dewpoint of the incoming and outgoing air was determined by the interjection of the base of a nickel test tube filled with ether into the air stream. When the ether and tube were cooled to the dewpoint of the air stream, the formation of a film of dew on the outside of the test tube could be seen. A delicate thermometer, having its bulb immersed in ether was then read to 0.1°, which is sufficiently accurate for all practical purposes.

As a result of the effect of evaporation, the dewpoint of the incoming air rises, and hence the transpiration can be calculated. Let y = rise in dewpoint of outgoing over that of incoming air; t = temperature of air; t_1 = dewpoint of incoming air; z = a constant, the value of which depends upon the rate of the air movement. The value of y may then be expressed by the formula $y = z\ (t - t_1)$.

The value of y is proportional to the temperature and increases with the rise of the latter. The agreement of this formula with the experimental results is shown in fig. 1 (p. 166). The line oy gives the calculated value of y. The dots show the experimental results obtained.

The author has been able by means of a series of experiments and calculations, and employing the same apparatus, to calculate the formula to determine the dewpoint in the case of variations in the speed of the air stream, the area of the evaporating surface or of the speed and area combined. The force of the current was measured according to the quantity of air which passed through the cylinder in a given time and was registered by a small gasometer.

The values calculated in this way correspond entirely to those obtained in the experiments.

APPLICATION OF THIS METHOD TO THE STUDY OF THE TRANSPIRATION OF LIVING PLANTS. — Fig. 2 (p. 167) gives the results of an experiment made with a potted alfalfa plant, varying the temperature and maintaining the air stream constant at 70.32 litres per hour, and the dewpoint of the exterior air at 4.8° C. The range of temperature was 17.8 to 36.1° ; the lines $o\ t$ and $o\ t_1$ give the values of t and t_1 respectively ; oy gives the calculated value of y when z (formula $y = z\ (t - t_1)$) equals 7.45 %.

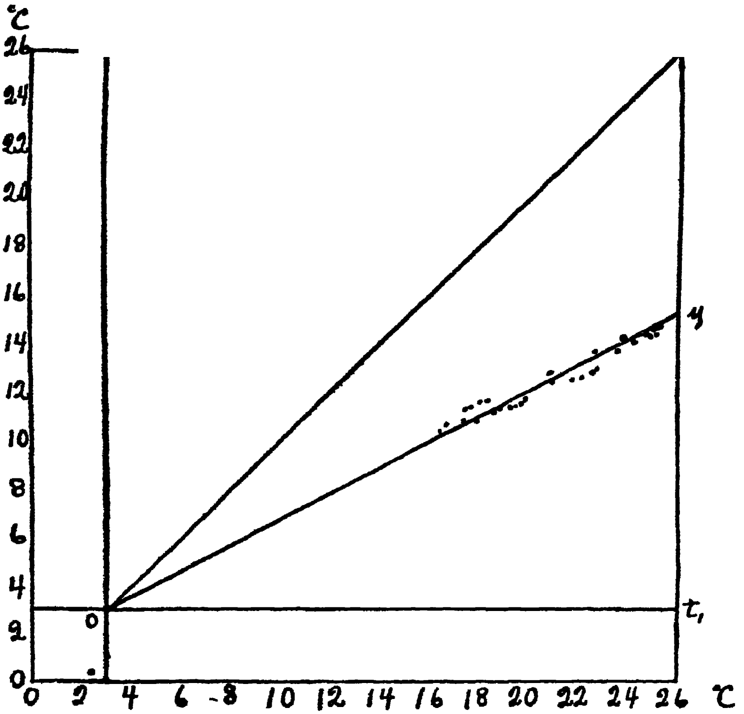

Fig. I.

The data obtained confirm the experimental result (see diagrams) and seem to indicate that under temperature changes of the magnitude here given, the plant acts essentially as a physical evaporating surface.

This method can be employed advantageously in the study of the comparative water loss from different varieties of a single species, and what is still more interesting, between each of the pure descendants of the same variety.

The following data refer to the two races 91 and 17 of alfalfa :—

Date	Race No.	Temperature in cylinder	Dew point of external air	Dew point of escaping air	Relative Humidity of escaping air	No. of sq. cm of leaves	Standard dew point	Excess of race No. 91

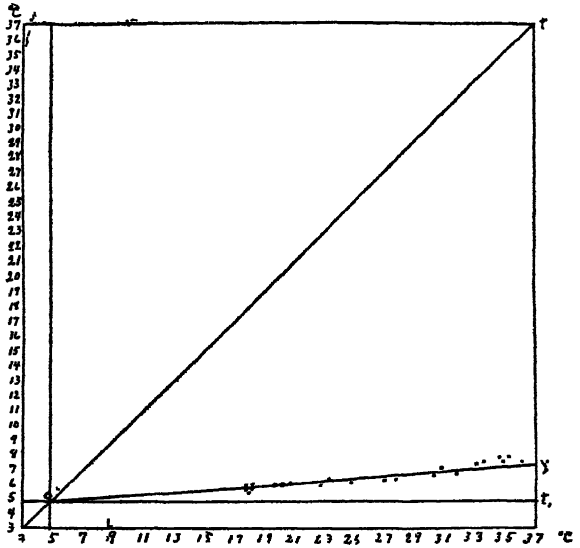

Fig. II.

There are evidently measurable differences in the rate of evaporation per unit area of the leaves of these two races, and this may prove of economic value in semi-arid or irrigated regions.

140 - **Action of Radiations of Different Wave Lengths upon Chlorophyll Assimilation.** — WURMSER, R., in the *Comptes rendus de l'Academie des Sciences*, Vol. CLXXI, No. 17, pp. 820-821. Paris, Oct., 26, 1920.

In a green plant exposed to the sun, a maximum of assilimation of approximately 680 $\mu\mu$ is admitted, but the existence of a second maximum found by ENGELMANN at about 480 $\mu\mu$, has always been disputed. The author has taken up the question, and has used a new method of measuring assimilation, the principle of which was first established by LOEB and OSTERHOUT. It consists in following by means of an indicator (phenolphthalein) the increase in alkalinity of sea-water in the presence of sea-weed exposed to light. The author used a green sea-weed, *Ulva lactuca,* and a red sea-weed, *Rhodymenia palmata.*

In the case of the green sea-weed exposed to day-light, he found that there were two maxima of assimilation. With an equal amount of energy absorbed, the blue radiations are more active than the red (at least 1·66 times). The return is highest in the region of least absorption. It thus seems that the oxygen produced by assimilation is not liberated upon contact with the chlorophyll grains, which would otherwise be rapidly destroyed. Protoplasm seems to be the active element in the reduction of CO_2. The speed of assimilation therefore ought to be so much the greater when, for the same quantity of energy absorbed, the active mass of protoplasm is greater. This happens in regions where a relatively thick layer is necessary to absorb this energy.

The red sea-weed, *Rhodymenia palmata,* assimilates with still greater energy in the green region, as is shown by the following figures, which deal with equal conditions for the two sea-weeds :—

Speed of Assimilation.

	Red light $\lambda > 580\ \mu\mu$	Green light $\lambda = 580\text{-}460\ \mu\,\mu$	Blue light $\lambda < 460\ \mu\mu$
Ulva lactuca	100	24	80
Rhodymenia palmata.	100	50	18

141 - **The Excretion of Toxins from the Roots of Plants.** — MUKERJI, J. N., in *The Agricultural Journal of India*, Vol XV, Pt. V, pp. 502 507, Tables 3. Calcutta and London, Sept 1920.

Some years ago the conclusion was drawn by FLETCHER as a result of field and water culture experiments (1), that crop plants excrete substances from their roots which are toxic to other species as well as to themselves. As the water culture tests were performed with ordinary well water and without control tests, the author considered the evidence inconclusive and repeated the process by substituting the synthetic Knop nutrient solution for the well water :— (Calcium nitrate 4 gm ; magnesium sulphate, 1 gm; potassium nitrate, 1 gm; potassium chloride ·05 gm; ferric chloride traces, dissolved in 7 litres of distilled water; the total salt concentration of this solution being ·11 %) Control tests were also introduced to check results.

---

(1) *Mem. of Dept. of Agric. in India, Bot. Ser.*, II, No. 3.

A large number of wheat, *Cajanus*, and gram (*Bouteloua* sp.) seedlings were grown in this nutrient solution, and at the end of a certain period the solution was allowed to evaporate spontaneously until its volume was reduced to about $^1/_8$. The "blanks" were allowed to evaporate to $^1/_3$ and $^1/_4$ the original volume. Jars containing the nutrient solution but bearing no seedlings were also treated in an identical manner and constituted the "blanks." Seeds were then introduced into these concentrated solutions (wheat water etc.) supposed to contain the excretions of plant roots and the progress of crops grown in them was recorded.

The seedlings grown in the various concentrated solutions throve better than in the "blank" test solution, and those grown in distilled water fared best. These observations led to the conclusion that the positive results obtained in the FLETCHER experiments were probably due to the concentration of the salts present in the well water and not to toxic excretions. This was confirmed by an estimation of the "total solids" in the solutions, obtained in the present series of experiments; the values for which are set forth as follows:

Total solids in grams per 100 c.c. "for:— "wheat" water, 0.269, *Cajanus* water 0.154, "gram" water 0.226, blank" water 0.382, and distilled water, nil.

The withering in the case of all 3 crops was hastened with the increase of concentration of total solids.

Former investigations made by various experimentors are mentioned, showing the influence of nutrient solutions covering a wide range of concentration, upon the growth of young plants. The optimum concentration for maize appeared to be about, 0.3 %, and the same for barley and buckwheat. The best concentration for wheat seedlings was placed at 0·03 %. All tend to place the optimum strength of the solution at 0·3 % of total salts. The strength of the solution in the FLETCHER experiment worked out approximately to 1.12 %, a concentration which would doubtless prove toxic to any plant.

The author concludes as a result of his own experiments that the effects ascribed to toxic excretions are, in reality, due to the high concentration of salts in the solutions employed in the final stages of the experiment.

142 - **Researches upon Grafts of *Solanum* spp.** — DANIEL, L., in the *Comptes rendus de l'Académie des Sciences*, Vol. CLXXI, No. 22, pp. 1074-1076. Paris, Nov. 29, 1920.

In a previous paper (*Revue bretonne de Botanique*, 1910-1913), the author has shown that the potato, grafted upon other more or less closely related Solanaceae, produces aerial tubers. These tubers vary in number according to the species which is chosen as stock and they are especially abundant when the graft is made with the aubergine and still more with the tomato. In addition, this abnormal formation of tubers depends also upon the nature of the organs taken as scions and upon the environmental conditions, be they natural or due to the grafter.

In 1919, the author gathered about a hundred of these aerial tubers from stocks of the Fluke variety, of Saint-Malo, some grafted upon the tomato, others upon the aubergine. In March, 1920, the author planted these tubers, which he had succeeded in keeping in good condition, in the gardens of the Laboratory of Plant Biology at Rennes, with the intention of studying their comparative development. Although some of the tubers were of small size, all produced plants with leaves; naturally the largest furnished the most vigorous specimens. In July, the author found that plants arising from the graft on the tomato had completely preserved the characters of the variety; themselves early also, they were not distinguished by any particular specific character. On the other hand, those plants arising from the graft on the aubergine were divided into two groups connected by intermediaries; some, the most numerous, had kept the characteristics of the Fluke variety · the others, which were fairly numerous, had become late, and their foliage was still green in September whereas that of the first group had become dry for over a month Thus the aubergine stock, which is late and does not ripen its fruit well in the Armorican climate, had partially transmitted its lateness of vegetation to several aerial tubers of its graft. This transmission, comparable to the action of *Vitis rupestris* upon certain varieties of *Vitis vinifera*, had become hereditary in certain examples by asexual reproduction

Three specimens showed a still more curious heredity Withont a trace of any external influence whatsoever (wounds parasites, particular variation of the environment), there formed at one and the same time aerial tubers and subterranean tubers upon their vegetative apparatus; this simultaneous production did not noticeably reduce the yield of the underground tubers. The agamous inheritance of a character acquired by grafting was in this case particularly clear, although more exceptional than the late character of growth (1).

The author also found that in 1920 all the descendants of the grafted Fluke plant arising from aerial tubers were not attacked by *Phytophthora infestans*

In 1920, the author repeated his grafts of Solanaceae and in particular those of aubergine upon tomato From a scion of the long violet coloured aubergine grafted on the "Merveille des Marchés" tomato, whose fruit is smooth and flat, the author obtained fruits absolutely similar to those of the tomato scion except that they had retained their violet colour. The peduncle, lengthened in the controls, was notably shortened, thus approaching that of the scion tomato On other grafts there were at the same time elongated fruits, short and conical fruits, rounded fruits violet in colour.

---

(1) Agamous inheritance consequent upon grafting exists also in the vine, of which useful varieties produced by grafting have been able to be propagated and have been maintained by vegetative reproduction (*Author*)

The variation produced by the symbiosis was more or less complete according to the grafts and was besides exceptional, for the majority of the grafts had not changed.

These phenomena resemble and confirm those obtained by the author in Laboratory of Plant Biology at Fontainbleau in 1895.

At Fontainbleau the fruits of the aubergine were ribbed because the subject tomato scion was taken from plants with ribbed fruit; at Rennes, on this occasion the fruits had become round and smooth because the "Merveille des Marches" is not ribbed. Since the same family of aubergine was in question, there had been, in the 2 cases, a very distinct orientation in the direction of the stock. This orientation allows the influence exercised by one or other of the associates upon its conjoint to be recognised. But this influence does not always exist and the mutual reaction can show itself in other ways, whether by the transformation of a latent character into a dominant character and vice versa, whether by a formation of combinations either ancestral or even essentially new, or by the appearance of essentially new characters. All these phenomena, which the author includes under the general name of "asexual hybridisation" without, however, failing to distinguish between them, have a common origin; they arise from mutual or antagonistic reactions (1) which take place on the level of the callus and at variable distances from it.

143 - **The Inheritance of Glume Length and Grain Length in a Wheat Cross.** — ENGLEDOW, F. L., in *Journal of Genetics*, Vol. X, No. 2, pp. 110-132, Bibliography of 18 works. London, Aug. 1920.

Results of a series of experiments on the inheritance of glume length in a wheat cross, the inheritance of grain length which bears some definite relation to the former and appears to have a marked economic significance.

The author made crosses between *Triticum polonicum* and the variety of *Triticum durum* known as "Kubanka," and studied the parental stocks and the F_1, F_2 and F_3 progeny obtained.

INHERITANCE OF GRAIN LENGTH. — The symbols employed by the author to facilate reference are as follows: —

P = *Triticum polonicum.*

K = variety Kubanka

I = heterozygous glume type proceding from the cross P × K and is roughly speaking, intermediate between the two parents.

F_0. P = population of pure parental Polish type employed in the cross.

F_0. M_p (glume) = mean glume length of a population of parental *T. polonicum* origin.

F_0. σ_p (glume) = standard deviation of the glume length.

The biometrical values recorded, correspond to the total of 8 measurements.

PARENT VARIETIES. — The results obtained in 1913 and 1914 may be summarised as follows: —

---

(1) See *R.* April 1920, No. 403. (*Ed*)

Year	Variety	Mean glume length	σ	Number of observations
1913	*T. polonicum*	$F_0 . M_p = 28.6 \pm 0.34$	—	80
1914	»	$F_0 . M_p = 30.84 \pm 0.10$	3.784	600
1913	« Kubanka »	$F_0 . M_k - 11.23 \pm 0.24$	—	25
1914	»	$F_0 . M_k = 11.70 \pm 0.04$	1.260	400

F_1. — During 1914-19 the F_1 measurements were lost, but according to the author's observations and those of other investigators the F_1 mean occupied an intermediate position which was attributed to the glume length and the F_1 value was probably 21.27 mm.

F_2. — Although 530 F_2 plants were raised, only 487 of them furnished grain for the raising of an F_3 (See table) :—

Class means	No. of plants	Class means	No. of plants
9.5	12.5	20.5.	16.0
10.5	28.0	21.5.	13.5

18.5	35.0	29.5	
19.5	13.5	30.5.	1.0
		Totals	**467**

Two conclusions may be drawn from these data :

(1) Three glume-length types appear in F_2.

(2) None of these types corresponds exactly to the *T. polonicum* parent.

To distinguish between these 3 types, the author adopted the mathematical analytical method and thus calculated, the frequencies of the F_2 types were :—

	K	I	P
Number of plants	23.29 %	57.76 %	18.94 %
Modes	11.5 mm.	16.5 mm.	24.5 mm.

F_3. — The F_3 plants were kept in families, an F_3 family consisting of all the plants raised from the grain borne by any one F_2 mother plant.

From the nature of the F_3 family the genetic type of the corresponding F_2 plant was judged. Thus an F_3 family on which all the plants were P, must have originated from a homozygote P plant of the F_2. An F_3 family, however, containing plants of two or more types (*e. g.* P, I, and K ; or P and I, etc.) must have come from an F_2 plant that was heterozygous *i. e.* an I plant

In the sorting of the types of the F_3 families, measurable (quantitative) type standards were considered preferable to mere eye-judgment.

For an F_3 family regarded as K, the value of 15 5 mm was finally adopted as an upper limit However, every plant of every family proved to be to the judgment of the eye, of K type in appearance, even when the glume length was less than 15 5 mm. The metrical standard was therefore, thus far, applicable.

F_3 families were accepted as P if they contained no plant of glume length less than 19 5 mm. This was found, however, inadequate for practical purposes, and after full trial, the metrical standard was abandoned in the case of the Polish and instead eye-judgment was adopted. *T. polonicum* and Kubanka are so distinct in glume form, that the practised eye has little difficulty in separating the homozygote (K and P) from the heterozygotes (I).

According to the standards adopted the F_3 is constituted as follows . —

$$F_3 = \left\{\begin{array}{l} 114\ \text{K families} = 1237\ \text{plants} \\ 267\ \text{I families} = 2854\ \text{»} \\ 101\ \text{P families} = 1054\ \text{»} \end{array}\right\} = 5145\ \text{plants.}$$

Regarding all F_2 plants as simple heterozygotes, if in their F_3 families, there occurred more than one type, and denoting the heterozygote by the letter I, the F_2 ratio is :

K	I	P	Total
114 plants	267 plants	101 plants	482 plants
	55·39 %	20 95 %	100 %

A ratio of 1 2 : 1 therefore holds good among these types, on the assumption of a 1-factor difference.

Consequently as a working hypothesis it is assumed that either P or K possesses a factor for glume length which the other lacks, and that the heterozygote is, broadly speaking, intermediate between the parental forms.

INHERITANCE OF GRAIN LENGTH. — It has been ascertained that on any plants, K glumes were invariably accompanied by K grains, and similarly for I and for P. Consequently in F_2 and F_3 the classification by glumes was accepted as a classification by grains.

Grain lengths of parental varieties. (F_0.P and F_0 K). — In successive generations the grain length distributions were,

F_1. — Grain measurements were lost. From memory and from previously published investigations it is concluded that the heterozygote length is roughly intermediate between the parental ones.

F_2. — It should not be forgotten that the grain K, I or P implies the plant possessing analogous glume types, since it has been admitted that glume length and grain length are genetically inseparable and are governed by the same factor. Glume-length showed segregation in F_2 as was made clear by examination of the F_3 progenies of the F_2 plants. The vindication of this assumption necessitates a demonstration of the segregation of grain length in F_2 similar to that given for glume length.

Frequency distributions of grain lengths F_2 *and* F_3 *and parents.*

Totals	526	395	487	1644

The F_2 distribution is unimodal but it would appear that "shift" has occurred. The author considers that possibly the distribution consists of 3 constituents which lie very close on account of the shift, and which, by marked overlap, produce unimodality of the whole.

F_3. — The measurements and numbers of plants correspond with those for glume length.

It may so far be concluded that:—

(1) the one factor which governs the P-K glume difference also governs the P-K grain difference;

(2) "Shift" occurs, so that the P and K types as seen in F_2 (glume and grain) are numerically shifted forms of the true F_0 type.

The shifted values persist in F_3 (See Column 4 of preceding Table).

(3) In spite of the demands of the double fertilisation theory, the grain appears in so far as its length is concerned to belong to the same generation as the plant on which it is borne, *i. e.* grain length is a maternal character and segregates on the 1 : 2 : 1 basis in F_2.

CONCERNING THE APPARENT GENETIC INSEPARABILITY OF CERTAIN CHARACTERS IN THE CROSS. — Glume form like grain form is the resultant of a number of characteristics, and since the resultants are inseparable, so also must the constituents be inseparable.

A list of inseparable constituent characters is here given :—

1) Length of glume.
2) Ribs on main lamina of glume.
3) Shape of tip of glume.
4) Curvature of keel of glume.
5) Consistency of material of glume (P is " papery ", K is more rigid).
6) Length of grain.
7) Shape and size of cross-section of grain.
8) The angle at which the embryo of the grain is set in the endosperm.
9) Number and length of the hairs at the apex of the grain.

144 - **Some Superior Varieties of Swedish Barley obtained by Line Selection or by Hybridisation.** — NILSSON-EHLE, H., in the *Landtmannen Tidskrift for Landtmann*, Year II, No. 45, pp 723-724, and No. 46, pp 743-745. Stockholm, November, 1920.

NEW VARIETY OF BARLEY WELL-ADAPTED TO CONDITIONS IN SWEDEN. — This refers to variety " 0412 " obtained by selection, from Chevalier and surpassing it in yield, owing to its stronger straw and earlier maturity.

Compared with " Princess," one of the most favoured varieties at the present time, 0412 produces equally well, matures earlier and possesses stronger stems. There is a promise, therefore, of a distinctly satisfactory combination of characters; it is only slightly inferior to " Gullkorn " as regards date of maturity. This new type is also remarkably resistant to *Heterodera schachtii*, to which Gullkorn and Princess are, on the contrary, generally liable.

Practical cultivation trials carried out on a large scale from 1910-1919 in the Malmöhus district certainly confirm the above statements, and support the claim that 0412, like Princess and Gullkorn, is one of the best varieties tested so far in southern Sweden; these three types can reciprocally replace one another in accordance with the special local conditions, geological and climatic.

DEGREE OF RESISTANCE OF THE DIFFERENT VARIETIES OF BARLEY TO *Helminthosporium gramineum*. — Amongst the more common varieties distinct differences have been observed and controlled experimentally with regard to their resistance to *Helminthosporium*. The Tystofte Korsbyg variety (Danish) occupies the first place as regards resistance. In a series of tests carried out by D. PETERSON at Köpenhamm, Tystofte Printice showed 8 % of infected plants, Julibyg 8 %, Fredriksens Grad Byg, 23 % Karlsbyg, evidently the most liable to attack, 48 %. It might be possible, however, by the aid of opportune crosses, proceeding from Tystofte Korsbyg, to obtain resistant types, with other desirable characters at the same time.

In any case, the character of resistance is subject, like all other characters, to the phenomena of splitting which make the work of fixing the types a tedious process. By crossing types of an average resistance, transgression phenomena are often liable to occur with the appearance of plants that are more resistant than the most resistant parent and more susceptible than the most susceptible parent.

Thus, in the F_2 of the Chevalier × Gullkorn cross studied in 1919 at Åkarp (Sweden), a considerable number of infected plants were observed, whilst the parents were practically all immune; this may perhaps be due to local conditions, but in any case, this phenomenon should be kept in sight, as the possibility of a negative transgression cannot be excluded.

The investigations made by KIESSLING at Weihenstephan (Bavaria) confirm the results obtained by Danish and Swedish investigators. Although the actual percentage of diseased plants may vary in limited areas from one year to another and from one locality to another, according to local conditions, the heredity of the character of resistance manifests itself each time with absolute certanty. The investigations made by KIESSLING also demonstrate the existence of resistant and susceptible varieties in every group; *nutans*, *erectum*, etc. The general opinion that attributes the most marked degree of susceptibility to the *erectum* type is completely erroneous.

Resistance can evidently be associated with morphological characters which serve to differentiate between the various groups.

RESISTANCE TO *Heterodera schachtii* AND ITS SIGNIFICANCE FROM THE PRACTICAL AGRICULTURAL STANDPOINT. — This nematode, as is welknown, has a considerable influence on the crop rotations adopted in Swe-den (especially on miocene clays) and in the Danish islands. Oats are obviously the most susceptible, although the other cereals may also be attacked. The most efficacious means of control used up to the present consists in intercalating hoed root crops *e. g.*, sugar beet in the rotation or other refractory crops such as leguminoseae. However, this method is not really sufficient, one reason being that certain forage Gramineae included in the rotation are also to some extent liable to attack.

It is therefore important, from the economic standpoint, to be able to make use of grasses that are completely refractory, as catch crops in rotation with beets and legumes.

A fact worthy of attention is that, up till now, no difference has been observed with respect to *Heterodera*, between the different varieties or types of wheat or oats, as all possess practically the same degree of susceptibility.

Distinct differences are evident, however, between the various sorts of barley at present cultivated. The first symptoms of this were revealed by the fact that the yield of oats varies according to the variety of barley which precedes it in the rotation. In fact, a long series of cultural tests at Skania showed that the yield of oats varied from 2900 kg. per hectare to 1800 kg., according to whether the oat crop had been preceded by resistant or susceptible types of barley.

The choice of varieties of barley resistant to *Heterodera* is therefore possible and is of the greatest importance from the economic point of view.

The Chevalier variety as well as Primus, Svanhals and 0412, is refractory but has the disadvantage that it produces less, matures late, and has somewhat weak straw.

The best producers, Gullkorn and Princess, are, on the contrary, very susceptible.

The researches undertaken by the author appear to indicate that resistance depends on a single genetic factor and as the characters of earliness, strong straw, etc, can easily be separated and re-combined, it will not be impossible to obtain, after a certain time, by means of crosses and suitable selection, etc., types which, being resistant to *Heterodera*, possess also to a marked degree the other desirable characteristics.

Attention is drawn in this respect to the researches made by ORTON in the United States. In the Southern areas, *Vigna sinensis* is largely cultivated: but certain types of *V. sinensis* are refractory to another nematode very injurious to the cotton, namely, *Heterodera radicicola*. If this resistant variety is introduced into the rotation, the damage caused by *Heterodera* to the cotton plantations can be considerably attenuated.

" ASPLUND " BARLEY. — In 1903, G. ASPLUND, of Viby, Västmanland (Sweden), noticed in a field of barley of the Primus variety, mixed with common 6-row barley, a plant which could be distinguished from all the others by its peculiar characteristics. This plant was isolated and reproduced until it was eventually introduced to the trade in 1910 by the Seed Association of Hälland; this variety has also been introduced and tested in Denmark, and particularly in Norway, where it gave excellent results. " Asplund " is distinguished by its high content of starch and fats, but it does not reach quite the same standard as regards proteins. Its good qualities, and particularly its short and strong straw, show up on very rich and well manured land, and under moist climatic conditions. This last circumstance accounts for the popularity and wide distribution of this new variety in the very moist southern and western districts of Norway.

As to its origin, it appears possible that it proceeds from a natural cross between Primus and the Common 6-row barley (indigenous to Northern Sweden), which, as already mentioned, was found more or less in combination in the field where the original plant was found.

The high yield may thus derive from Primus and the early ripening from the native barley; the latter quality makes it possible to grow this new variety successfully very far to the north.

The author intends to make a special study of the origin of Asplund at the Genetic Institute (Southern Sweden).

145 - **Inheritance in Barley: The Lateral Florets and the Rachilla.** — ENGLEDOW, F. L., in *Journal of Genetics*, Vol. X, No. 2, pp. 93-108, Bibliography of 10 works. London, Aug. 1920.

In the barleys, the rachilla may be bristly, well supplied with long hairs or smooth with short fine hairs. From the cross *Russian Chevalier* No. 7 × *English Archer*, 2 rows of both, the first smooth and the second bristly, in the F_1 bristly plants were obtained (*Archer* type) and in F_2 out of 546 plants, the ratio was bristly: smooth = 410: 136 (3:1 ratio).

In a similar way, the cross *Russian Goldthorpe* No. 10 × *Inerme* gave in F_1 bristly (*inerme* type), and in F_2 bristly and smooth ratio, 3 : 1.

The presence or absence of hairs on the rachilla is then, governed by one factor.

A series of crosses between barley varieties (2-row) and others (6 row) demonstrated that different forms of lateral floret in hybrid generations exist distinct from the parent forms. Taking as example *H. hexastichum*;

(*A*) Lateral floret always fertile, the grain being nearly as large as that formed by the median floret; *distichum* barley (*F* type) non fertile; outer palea always rounded and awnless; stamens and a very small shapeless ovary.

In hybrid generations, there are apparently certain forms which have no connection with any of the parents. The following types exist:

(*C*) Fertile; grain small; outer palea terminating in an awn which may be merely a point or up to 3 cm. long. This type appears to be a heterozygote.

(*D*) Non-fertile, but inflated; outer palea pointed or with short awns; stamens and reduced ovary.

E) Non-fertile, but large and inflated; outer palea always rounded and devoid of an awn; stamens and reduced ovary.

G) Non-fertile and extremely reduced; small outer palea and a rudimentary inner one; no traces of rachilla or reproductive organs.

The F_2 type of lateral floret obtained by cross between 2-row and 6-row barley gave as average:

Homozygote (*A*) 6-row	398 plants
Heterozygote	821 »
Homozygote (*F*) 2-row	392 »

Ratio 1 : 2 : 1.

146 – **The Inheritance of an Abnormal Haulm Type in Potatoes.** — SALAMAN, R. N., and LESLEY, J. W., in *Journal of Genetics*, Vol 10, No 1, pp. 21-36 Pl 2. London, July, 1920.

In 1906 the potato variety Queen of the Valley was fertilised by Flourball. One of the F_1 seedlings was fertilised in its turn by a seedling arising from a selfed ball of Bohemian Pearl. This gave rise to a family which was grown in 1909, one of whose units (M_5 B_{35}), selfed in that year and produced a type characterised by a " prostrate " habit.

The stems instead of standing erect, lay along the ground; When handled the stems themselves felt like soft rubber tubes. The article under consideration contains the results of study both anatomical and genetical, in connection with this new type.

I. ANATOMICAL STRUCTURE. — The most outstanding difference between the normal and abnormal type is associated with the xylem, which with a normal stem forms a continuous ring of woody tissue in the interfascicular region or medullary rays; the xylem in the second case was either deficient or entirely wanting. Owing to the deficiency of sclerosed tissue, the stems were not capable of remaining upright and were obliged to creep horizontally along the ground.

GENETIC RELATIONS. — The origin of the "prostrate" plants may be traced back to 3 cultivated varieties. Flourball, Queen of the Valley and Bohemian Pearl; the direct parent stock M_5 B_{35} mentioned above has been lost. In the study of the genetical characters, attention is therefore confined to the progeny. The "prostrate" variety not only breeds true but reproduces itself without variation through the buds of its tubers.

The authors made crosses of type Upright × Prostrate, and Prostrate upright, choosing specimens in which the differential character is fixed and constant from the genetical standpoint.

In F_1, 914 upright and 13 prostrate were obtained.

(The 13 Prostrates were partly derived from 3 families possessing the following ratio: Upright: Prostrate = 79 : 6; 39 : 6 and 91 : 1.).

The normal upright character evidently behaves as a dominant. The incomplete dominance observed in the 3 F_1 families mentioned, may possibly have been due to faulty technique during the pollination process.

In F_2, 826 upright to 13 prostrate were notified, or approximately 63 : 1. The selfed F_2 plants gave in F_3, upright and prostrate in the following proportions: —

Upright	Prostrate	Upright	Prostrate
10	3	26	—
35	1	9	—
38	3	7	1
24	—	—	—

Now, if, as the proportion in F_2 led us to suppose, the "upright" and "prostrate" parents differ in 3 factors, any one of which in a single dose gives "uprightness," F^2 uprights when selfed should prove of 4 distinct kinds: pure "uprights"; impure "uprights" of 3 distinct kinds. More than half $\left(\frac{37}{63}\right)$ will be pure "upright"; the remainder $\left(\frac{26}{63}\right)$ impure; of these latter nearly half $\left(\frac{12}{26}\right)$ will yield "uprights" and "prostrates" in the ratio of 15 : 1, about one third $\left(\frac{8}{26}\right)$ should give 63 : 1, and the remainder $\left(\frac{6}{26}\right)$ 3 : 1.

The data collected clearly indicate the phenomena of segregation of characters; however, the material so far analysed is insufficient to construct any definite gametic formulae.

CONCLUSION. — The procumbent "prostrate" variety is associated with a deficiency of xylem. The differential character is determined by several factors, probably 3 in number.

147 - **Hybridisation Trials with Certain Lines of Deli Tobacco, at Medan, Sumatra.** — HONING, J A, in the *Mededeelingen van het Deli Proefstation*, Series 2, No. X, pp 1-41. Medan, 1920.

Results of several hybridisation trials with the following strains of Deli tobacco: —

Light brown No. 72: — Abundant foliage; brown colour after fermentation.

Line 774: — Many elongated leaves, but somewhat narrow at the base; late flowering.

Pale No. 1: — Leaf blades light — coloured, shining, long and wide, especially at the base; after fermentation, turning light brown or reddish green.

Dark. No. 3: — Leaf blade rather shorter and darker (brownish-green, reddish-brown) than Line No. 1.

I. — From the cross between the 2 lines, Nos. 1 and 3, in F_1, the progeny was homogeneous and possessed intermediate characters. In F_2 and F_3, a dissociation of characters was evident with the appearance of intermediate individuals and individuals showing the parental characters.

II. — Cross No. 1 × No. 72. No 1 possesses the advantage over No. 72 of having somewhat thicker foliage and very long blades. No. 72 possesses, however, abundant foliage and a good colour. The cross was made for the purpose of combining, if possible, the characters of the 2 lines in one fixed type.

The hybrids of F_1 produce on an average 1 or 2 leaves more than strain No. 1. As to the length and width of the leaves, these are very similar to those in line No. 1, whilst the number of dark leaves is greater with the hybrids than with No. 1.

It may be concluded that the hybrid descendants give in F_2 a mixture of types, some of which closely resemble the parents. Several characters are combined and limit the possibility of obtaining positive results by means of hybridisation; for example, plants with leaves broad at the base flower earlier than those with a constricted base.

III. — Cross. No. 1 × No. 774 is characterised by a larger number of leaves (8 or 9), by a more constricted leaf-base and by late flowering. In F_1, and F_2, roughly the same number of leaves are produced as in No. 1, The character "numerous leaves" appears to be completely dominant. As regards length of leaf blades, the F_2 resembles No. 1 (slightly behind as compared with No. 774) and, as regards width it has intermediate characters, although the differences are negligible.

Most of the F_2 progeny have the narrow leaves of the parent No. 774; the data apparently indicate that there is a segregation of characters regulated by two factors, and that the character "c ns ricted base" is dominant. Here also the latter character remains united to the character "late flowering," and perhaps even to the character "abundant foliage".

148 - **Bud Variations of Cultivated Trees and Shrubs as the Cause of the Deterioration of Fruit-Tree Varieties.** — CHEVALIER, A. (Directeur du Laboratoire d'Agronomie Coloniale de l'École pratique des hautes études), in the *Comptes rendus de l'Académie des Sciences*, Vol. CLXXI, No. 21, pp. 1011-1014. Paris, Nov. 22, 1920.

Bud variations often due to heredity occupy a high position in the plant world, as is shown by the important bibliography dealing with this subject by P. J. S. CRAMER (*Kritische Uebersicht der bekannten Fäll von Knospenvariation*, Haarlem, 1907). Attention has since been particularly drawn to the improved new varieties derived from bud variations in cultivated plants that have been propagated asexually from remote periods, *e. g.*, banana, sugar cane, potato, etc.

The author sets out to demonstrate that bud variation is also a cause of the deterioration of improved varieties propagated asexually for many years. These variations occur unexpectedly as the tree becomes old, as BLARINGHEM has shown (Les complexes végétaux et leurs disjonctions par la veillesse, *Annales de l'Institut Pasteur*, Vol. 32, No. 2, Feb., 1918), or through mishap, lack of care, or even after the transport of the individual tree far from its native country.

With reference the maple with variegated leaves (*Acer Negundo* L. var. *foliis argenteo-variegatis* Hort.), it is only rarely that green suckers are formed. Nevertheless, this variety occasionally shows a tendency to revert to the type with green leaves. In the summer of 1920, during a visit to the devastated areas, the author noticed that, at Saint-Quentin at la Fère and at Noyon, all the Negundo maples with silver leaves, growing in the invaded area, with lopped branches and in a generally dilapidated condition, produced a large number of branches with green leaves. One mutilated specimen growing at Noyon, outside the cathedral, was especially noticeable in this respect. In October last, it produced at the same time branches with variegated leaves and others with green leaves intermingled, indicating, therefore, a veritable disjunction. The two types of branches bore normally developed fruit.

In Paris, a species of *Myrtus communis* L. with large opposite leaves, is grown, propagated sôlely by cuttings. On a specimen at Domfront (Orne), the author noted the appearance of a feeble branch with verticillate leaves in threes, thus resembling the variety used in Jewish cermonies (H. DE VRIES).

In Normandy the author observed also a Bigarreau Cherry, nearly a hundred years old, with a branch that had fruit spurs, bearing small bitter cherries, and a pear tree without thorns with some branches that bore fruiting branches with thorns, evidently a reversion to the ancestral type *Pyrus Pyraster* Borau.

Certain old varieties of the cider apple, propagated exclusively by grafting for several centuries, have remained unchanged in certain localities, whilst in others, they are on the downward grade (less fertility, less resistance to disease). The olive which has been propagated asexually since the very earliest times, has reached a state of senility, whch frequently leads to the formation of excrescences, true bud variations that imply the decadence of the varieties both physiologically and sometimes morphologically.

It is therefore necessary to regenerate the varieties cultivated since ancient times and to attempt to reproduce them by self-pollination and from seed. When selecting a grafting stock, it is necessary to make sure that the branch from which it is proposed to remove the graft possesses the true characters of the variety in question. The grafts should thus be taken from young and vigorous stock and all those coming from suckers or from excrescences or from fallen branches should be discarded.

149 – **Methods for Differentiating between the Seed of Mangolds and Sugar-Beets** (1). — PIEPER, H., in the *Zeitschrift des Vereins der Deutschen Zuckerindustrie*, Nov. 1919; reproduced in *Deutsche Landwirtschaftliche Presse*, No 1, pp 3-4, 1920.

In most cases, the glomerulae of the mangold can be readily distinguished from those of the sugar-beet after germination (not before), by the colour of the plumule, above and below ground, by the radicle leaves, etc.

It is sufficient therefore to conduct germination tests by burying the seeds 2 cm. deep in small receptacles containing garden soil, exposed to diffused light, covered with sheets of glass (uncoloured) and at a temperature of 15° C. After 8 days, when the first shoots appear the sheets of glass should be removed, and the seedlings watered, if necessary. After 2 or 3 weeks, the seedlings are 2 to 3 cm. high and the process is ended.

For examination purposes, the seedlings are pulled up whole and examined individually on a black plate, comparing them with seedlings possessing definite characters proper to the sugar-beet.

In the sugar beets, the hypcotyl is colourless and the epigeal portion is generally (80 %) rose-coloured or greenish white (some 20 %).

In mangolds with yellow or orange coloured roots, the stems are either entirely yellow, or distinctly orange, with slight shades.

In mangolds with red roots, the stems are distinctly carmine in colour which increases in intensity from the first foliage leaves downwards.

The only mangolds which may be confused with sugar beets are those with white roots and the Lank variety, owing to the similarity in stem coloration.

150 – **Varietal Experiments with Spring Wheat on the Northern Great Plains** (2). — CLARK, J. A., MARTIN, J. H. and SMITH, R. W. (Office of Cereal Investigations) in the *United States Department of Agriculture, Bulletin* No. 878, pp. 1-47, Tables XXI, Pl. 3, Bibliogr. of 15 works. Washington, D. C., Nov. 9, 1920.

A summary of the results from " Field Stations ". The average annual precipitation at the various Stations during the period 1913-1919, inclusive, was between 13 and 19 inches. These experiments were conducted in order to determine the varieties best adapted for growing in this semi-arid region. Drought and diseases occurred in several of the years, causing premature ripening, low yields and poor quality of wheat. By means of the complete records kept, in addition to yield, data on the following important factors were obtained concerning days from emergence to maturity, height of plant, percentage of stem rust infection, weight per bushel, percentage of crude protein, yield of flour, and volume of loaf.

---

(1) Method first adopted by the *Verein der deutschen Zuckerindustrie.*

(2) See *R.* Sept. 1915, No. 907 and *R.* March 1917, No. 237. (*Ed.*)

Two classes of wheat were grown, namely common and durum. The former was represented by hard red spring varieties considered best for bread making. The latter generally gave a higher yield and were more resistant to rust and drought, but although in in some cases yielding a higher percentage of flour than common wheat, equal or superior to the latter in crude protein, they possessed a weak gluten.

A comparison of the various results showed that in general, the Marquis (1) was the leading yielding variety amongst the common wheats. It is short strawed, early maturing and has the highest milling and breadmaking value. (The average yield of flour from 37 samples was 70.2 %) This variety was therefore used by the authors as the standard of comparison Of the other commercial varieties the Power Fife with an only slightly inferior milling value, gave larger yield and greater height than Marquis in north-western North Dakota and north-eastern Montana. The Preston yielded less, was more liable to rust, but matured nearly as early, and had a greater bushel weight. Few new varieties compared favourably with Marquis The early maturing varieties Prelude and Pioneer escaped summer drought in some seasons and possessed good milling and baking value. In a limited number of Experiments, Kitchener, Ruby and Kota varieties showed promise of being even superior in quality to Marquis.

Of the two widely grown commercial varieties of durum wheat, Arnautka and Kubanka, the latter proved superior in yield, rust, resistance, and milling and baking value. The Poliss gave the highest yield in the western portion of the Great Plains area. The Acme and Monad were superior and showed the highest percentages of flour of any of the durum wheats, as compared with Marquis, being higher by 2.5 % and 2.4 % respectively. The D-S variety (Red Durum) was the most rust resistant variety grown but had poor milling value.

151 - **Qualities of Some Selected Swedish Barley Varieties.** — See No 144 of this *Review*

152 - **The Growth of Rice as Related to Proportions of Fertiliser Salts added to Soil Cultures.** — TRELEASE, S F. (Department of Plant Physiology, College of Agriculture, Los Baños), in *The Philippine Journal of Science*, Vol. 16, No. 6, pp. 603-627, Fig. 5, Bibliogr. of 16 works. Manila, June 1920.

The author deals with the growth of rice plants in soil cultures to which phosphorous, nitrogen and potassium were added in various proportions. The addition of these elements was made by means of three salts namely: primary calcium phosphate (Ca $(HPO_4)_2$ ammonium sulphate $(NH_4)_2 SO_4$) and potassium sulphate ($K_2 SO_4$).

For these tests rice was employed (variety "sanglay puti") growing in a water-saturated soil, in culture vessels having a capacity of approximately 19 litres each. To each culture a sufficient quantity of salts was added to give in 19 litres of water a total osmotic concentration of approximately 0.5 atmosphere at 25° C.

---

(1) See *R.* June 1918, No 641, and *R.* Dec. 1918, No 1349 and *R.* Feb. 1919, No 190 (*Ed.*)

Results. — The plants in all of the cultures made vigorous growth compared with the control cultures. The colour differences became conspicuous about 3 weeks after trasnsplanting. At this time the cultures having 0.1. and 0.2 of their total osmotic concentration due to ammonium sulphate were small and were light green in colour; those having 0.3, 0.4 and 0.5 due to a similar cause were a medium shade of green; and the cultures having 0 6, 0.7 and 0.8 of their total concentration due to this salt were a very dark shade of green. The plants that were medium and dark were apparently the most vigorous and made the most rapid vegetative growth, and produced the largest number of stools and the broadest leaves. These differences in colour remained noticeable until several weeks after the time of flowering, when all the cultures became yellower in colour and the differences less marked.

The triangular diagram showing the relative dry yields of tops brings out some interesting relations between the proportions of the salts supplied to the soil and the resulting plant growth as indicated by the production of dry tops. The area of high yields includes the cultures characteriseed by the highest proportions of $(NH_4)_2\ SO_4$ and it is evident that no high yields were obtained when this salt made up less than 0.4 of the total osmotic value of the salt mixture nor when $Ca\ (H\ PO_4)_2$ comprised more than 0.5 of the said value. The highest yield of tops was obtained with a culture having the following fertiliser mixture: 0.0154 gm. molecule of $Ca\ (HPO_4)_2$ 0.1228 gm, molecule of $(NH_4)_2\ SO_4$, and 0.0154 gm. molecule of $K_2\ SO_4$. The yield of tops with the control culture, which was without fertiliser was only 19 % of that obtained with the above mentioned culture. The highest grain yield was also obtained with this culture.

The lowest yield of tops and also of grain were obtained with cultures containing the lowest proportion of $(NH_4)_2\ SO_4$ tested, and low proportions of $Ca\ (H\ PO_4)_2$, but with high proportions of $K_2\ SO_4$. A very slight, but probably not significant, improvement resulted from the addition of these poorest salt mixtures to the soil, since the grain yield obtained was slightly higher than the average yield from the control cultures

A comparison between different kinds of plant neasurement is illustrated in graph form.

In the study reported by the author only one total concentration of the fertiliser salts was tested, and it is suggested that similar experiments should be conducted with a range of total concentrations from the very low to the very high values, in order to make it possible to determine approximately, the optimum proportions of the fertiliser salts at the optimum total concentration and consequently the best proportions for the growth of rice plants under the general conditions of these experiments. The importance of further investigations in this respect is emphasised.

153 - **Importance of Lupin Cultivation.** — See No. 119 of this *Review.*

154 - **Modifications in the Usual Form of Cultivation of Potatoes.** — Schribaux, in *Comptes rendus de l'Académie d'Agriculture de France*, Vol VI, No 39, pp 930 934 Paris, Dec 22, 1920

Report of information received from Dr Maisonneuve giving an account of comparative tests carried out at Angers with the potato, using 1) whole sets · 2) cut sets weighing 8 to 10 gm with one eye

The cut sets were exposed to the sun for 102 days, in order to allow the wounds to callus, and were then planted in rows 12-14 cm between the sets

Four experiments out of 5 gave results indicating that small and medium cut sets give higher yields than whole sets In the first test, the medium cut sets produced 40 % more than the whole sets and gave larger tubers In the second test, the small cut sets gave 80 % more than the whole sets

M Schribaux remarks that he has already had the opportunity to notify similar results Evidently it has to do with a fertile area The question still lies open as to the behaviour of these different methods of cutting relative to various soils, weather conditions, varieties, etc

155 - **Brazilian Manioc.** — Guimarães, F, in the *Boletim do Ministerio da Agricultura, Industria e Commercio*, Year VIII, pp 167 170, Rio de Janeiro, 1920

Analyses were made of 5 specimens of Manioc (1), in the chemical Laboratory of the "Museo Nacional do Rio de Janeiro" The results obtained are set out in the following table —

Variety	Bark	Original material						Dry material				
		Moisture	Ash	Protein	Fats	Cellulose	Starch	Ash	Protein	Fats	Cellulose	Starch
	Per cent											
Yuca Maltingir (12 Months)	13 12	69 22	1 21	1 01	0 61	0 92	27 03	3 94	3 31	1 99	2 99	87 77

156 - **Cultivation and Use of " Kudzu" *(Pueraria Thunbergiana).*** — SIENT, S. M (Division of Botany, Pretoria), in the *Journal of the Department of Agriculture, Union of South Africa*, Vol. 1, No. 6 pp. 558-560. Pretoria, Sept. 1920.

This woody climber, Natural Order *Leguminosae*, is a native of Japan, where the starch in the roots is used for human food and the stems contain a fine fibre suitable for cloth manufacture, and the foliage is used as stock fodder, especially for horses. It has been cultivated as an ornamental plant in the United States but only quite recently as a forage crop. Reference is made to the experiments carried out at the Louisiana Agricultural Experiment Station etc. reported by PIPER (Department of Agriculture, Washington), who also lays special stress on the fact that although the value of the plant both for hay and grazing is acknowledged, investigations are still necessary to prove its habits and behaviour under varying conditions, before a definite opinion can be given. The feeding value is about equal to clover and lucerne.

Setting the rooted plants in the field where they are to be grown was found the best method, and preferable to seeding or propagation by cuttings. The largest crops were not obtained until the third season and subsequently. As " Kudzu " is a long-lived perennial it is advisable to plant it only where the field can hold this crop for several years. Soyabeans, cowpeas or peanuts can be grown between the rows during the first season, to avoid losing the use of the land.

The crop was found best suited to pasture land for cattle in preference to hogs, and was proved excellent for soiling and for green feeding. A yield as high as 10 tons per acre of hay was reported in Northern Florida, yielding three cuttings of hay per season. The hay cured more easily than most legumes, as the leaves are less juicy. If properly cocked, the hay shed rain without the use of any topping material. Even cocks left all the winter were only brown and weathered the following spring but the forage within was a bright green colour. Kudzu can be cut readily with a mower. The first mowing may prove difficult and an old scythe blade fastened vertically to the end of the cutter bar is advised.

The reports of experimental work in South Africa are given, but this is not extensive, and further trials are in process and the results will be reported later.

157 - **The Castor-Oil Plant of Cyrenaica.** — SCAETTA, H., in *L'Italia Agricola*, Year LVII, No. 11. pp. 331-333 + 1 fig. Piacenza, Nov., 15, 1920.

In Cyrenaica, the wild castor plant frequently grows as large as a tree, that is, to a height of about 5-6 metres. The only varieties which seem to exist there are *Ricinus communis minor*, *R. sanguineus*, and *R. viridis*. The first grows in mellow land which is not extremely arid. The second variety has been seen by the author on the Fetejah plateau, growing under perfectly arid conditions, in rocky soil and in the valleys of certain ouadi.

The plant is normally monoecious; the same inflorescence carries male flowers at the base and female flowers at the tip. The male flowers sometimes grow around a single female flower.

The average length of the inflorescence is 25 cm. The fruits are dehiscent in var. *minor* and indehiscent in the var. *sanguineus*. The appearance of the plant is characteristic. In the oases, near the small irrigation canals, it grows so rapidly that in 2 years it is as big as a tree, with large, light-green leaves with long petioles, and branches with elongated internodes. In dry soil, however, whilst still retaining the tree-like aspect, the leaves are smaller and thinner and the internodes are shorter.

R. sanguineus, as observed on the arid, compact soil of the plateau has a low habit, is branched near the base, and has a red stem, and leaves, and inflorescences covered with fruit, whose red berries are speckled with brown, about 15 mm. long, 8 mm. wide, and 5-7 mm. in thickness.

Although the *minor* variety is generally cultivated, and yields more abundant and finer oil, it is, however, of secondary importance to Cyrenaica as it can only grow in cool soil or with the help of irrigation, i. e. on very limited areas. On the contrary, *R. sanguineus* manifests, in Cyrenaica, a great resistance to drought and winds; it seems as if the heat of summer and the aridity of the ghibli facilitate the maturation and dehiscence of the fruit. Even during experiments made in Algeria and Senegal this plant resisted heat and drought. The castor-oil plant is not cultivated by the natives. In 1920, experiments were commenced in Cyrenaica with *R. sanguineus*, without irrigation.

158 - ***Saccharum spontaneum*** (1). — RIVIÈRE, C., in the *Comptes rendus de l'Académie d'Agriculture de France*, Vol. VI, No. 38, pp. 912-916. Paris, Dec. 15, 1920.

Saccharum spontaneum L. = *S. aegyptiacum* Wild = *S. biflorum* Forskal is a plant that grows to a height of between 2-3 metres, sometimes more, and has perennial, abundant foliage. Found wild in many parts of the world, it is spreading in the eastern basin of the Mediterranean. However it is found in small and rare patches in the neighbourhood of Bône, Algeria.

This strong perennial plant, bushy and spreading is easily propagated and is chiefly used for fixing sand-dunes either on the sea-shore or in the desert, but where the temperature falls but slightly below zero.

It is now 50 years since the author introduced, cultivated and wrote about this plant in the Experimental Garden, at Algiers. Although growing wild on the dunes, this *Saccharum* does quite well in compact soils, but prefers light soils with a damp substrate. The regions most favourable to its growth are the shore and low marine climates, then the low deserts, for the High Plateaux do not suit it as the temperature falls below zero.

The cultivation of this species is extremely easy. Propagation is effected by simple division or splitting of the rhizome 25-30 cm. long, leaving one or two pieces of stem; it is then planted in a shallow furrow. The spacing of the lines and plants can be varied at wish, but the spreading tendency of the roots of this species must be remembered. The plant strikes quickly and resists prolonged drought, but irrigation or watering will encourage a much more rapid growth

---

(1) See *R.*, June, 1920, No. 652. (*Ed.*)

Two economical methods are now adopted:—

(1) The *Saccharum*, although rhizomatous, is, on account of its dense growth, an excellent plant for improving low and marshy land, for it soon covers it and dries it up; it can also be planted along water-courses, for it protects the banks against erosion as it does the dunes.

(2) In damp or watered soil, this plant, especially the young shoots, makes a fodder, that is appreciated by cattle, camels and asses, which are usually easy to please as regards food in certain seasons. If the plant has grown too much and has become leathery, with sharp leaves, it should be made into silage. If aided by watering an abundant yield can be obtained by successive cuttings.

The utility of this plant is great, as the stems, 3 metres high, can be cut twice a year and used to make fences, wind-screens, roofs, furniture, packing, etc. But the plant should not be cultivated as a wind-screen, for not only will it spread into the crops, but it harbours a very harmful insect.

This *Saccharum*, like sorghum, sugar-cane, maize, and other big gramineae, is subject to attack by a very prolific lepidopteron, *Sesamia nonagrioides* Lefèvre, which leaves it in the larval stage and spreads into and ravages all the food crops, especially herbaceous ones. It is also unwise to plant this species around vineyards because the vines will be exposed to attacks from *Sesamia nonagrioides* which are more active and more to be feared than those of the " altise ".

The insects, which emerge from the dry stems of the *Saccharum* when used as coverings of fences against the sun or wind will rapidly destroy market-garden crops and even damage extremely rare horticultural specimens.

159 - **Low Temperatures in Floriculture.** — MARINO, A., in the *Rivista del Freddo*, Year VI, No 8, pp 277-278 Rome, Aug., 1920.

From the floricultural point of view the chief points of interest for the refrigerating industry are:— 1) To be able to retard the growth and, consequently, the flowering of plants; 2) to be able to preserve the flower as long as possible.

The following facts have been deduced from practical observations:—

The lily-of-the-valley flowers quickly, and arrives at maturity about 3 weeks after being taken from the refrigerator. Spiraea matures in 6 or 7 weeks, *Azalea mollis* Bl. (*Rhododendron molle* G. Don) in 5 or 6 weeks. The different species of *Lilium* (*longifolium*, *auratum*, and *tenuifolium*) flower, the first after 13-15 weeks, the second after 16-18 weeks, the third after 18-20 weeks. *Lilium longifolium*, potted in the summer, flowers in 16-18 weeks. Usually, lily bulbs potted after the middle of September flower, 1, 2, or 3 weeks after, according to the time of potting, but this should not be later than the second week in November.

The temperatures to which the young plants can be subjected vary.

Lilium candidum bulbs will stand −2.2° C., those of *Lilium longiflorum* must be kept at a constant temperature which should not exceed 15°C., and when they bear shoots the temperature should be raised to 18°C. in the greenhouse and 21°C. in the sun. *L. auratum* bulbs can be kept in drained pots with dry earth at 13°C. until they sprout, then at 20°C., until they flower.

The lilac and lily-of-the-valley (rhizomes and young plants) should be kept at a minimum temperature of −8°C. and at a maximum of −5°C. Rose trees can be kept from November to March at 6-10°C.; they can thus be kept from the frosts and all growth is stopped until spring is well advanced.

Dutch hyacinth bulbs are kept at 0.5°C. The hygrometric degree at which bulbs, rhizomes and young plants are usually kept is from 80-90 %. In the case of cut flowers the facts are as follows:—

Astrea keeps well for 35 days, at a hygrometric degree of 85 %. Chrysanthemums 45 days, with 90 % or more humidity.

The iris is difficult to keep, and resists at most for 12 days at 2°C. with 85 % of relative humidity.

The hyacinth keeps well for more than a month at 2°C. and 85 % relative humidity:

White lilac keeps better than the coloured varieties: about 30 days.

Lilies (especially *L. candidum*) when not quite open, keep 30 days at 2°C. with 80 % hygrometric degree. Narcissi, violets and tulips keep more than a month, better as buds or slightly closed, at 3° C. and 85 % relative humidity.

The rose shews little resistance to cold, but buds will keep 8 days at 2° C. and 85-90 % relative humidity.

The flowers for conservation should be plucked on days that are neither too hot nor too dry, and put into the refrigerator immediately.

160 - **Edible Fruit of the Madagascar Katoka Tree (*Treculia* sp.).** — JUMELLE, H., in the *Comptes rendus de l'Académie des Sciences*, Vol. CLXXI, No. 19, pp. 924-926. Paris, Nov., 1920.

The commercial interest which, in 1920 was taken in the "katoka" fruit imported from Western Madagascar has led the author to study the botanical origin of this fruit. The type cultivated is an artocarpus, which the author considers as new, belonging to the genus *Treculia* He has named it *T. Perrieri* and it is related to the jaca and bread-fruit.

The katoka, called "Tabory" or "Stipa" by the Sakalaves, is a tree which grows to a height of 30 metres; the trunk, deeply furrowed, has a smooth and greyish bark. The leaves are persistent. It flowers in October, and the fruits ripen in January and February.

Treculia is generally considered to be dioeceous.

M. P. DE LA BATHIE admits, however, that the katoka may also be monoeceous. Usually the male thalami are on the young branches and the female receptacles on the older branches. When mature the female thalamus becomes a sessile syncarpium or false fruit, fairly irregular in form, like the jaca. It attains more than 30 cm. in diameter and weighs up to, and over, 5 kg. It is fleshy and contains, near the surface, 6 or 7 layers of oval achenes, the size of small nuts.

T. Perrieri is common in the west of Madagascar in damp woods, below an altitude of 300 metres, on the alluvia of all the rivers from the extreme north to south. It appears to be lacking in Samberano only. The white wood is very good, and is used locally for making spoons and other small household utensils.

The fruit is usually said to be an oil-seed and has been sold as such in Marseilles, but it is really more starchy than oil-bearing. They are edible, with a good taste, and are eaten by the Madagascans. The yield of this tree is about equal to that of the jaca tree.

161 – **Plant Propagation and Fruit Culture in the Tropics.** — WESTER, P. J., in *Bulletin No. 32, Government of the Philippine Islands, Department of Agriculture and Natural Resources, Bureau of Agriculture*, pp. 9-134 Pl. XXIII + figs. 53. Manila, 1920.

Details are given of plant and propagation sheds, nursery accessories, the principles and various methods of propagation by seed, cuttings, layering, grafting and budding, and directions for the vegetative propagation of tropical and semi-tropical plants, and also for tree planting and orchard management. The methods of selecting shade trees and ornamental plants are given, followed by preliminary remarks as to plant pests and diseases injurious to orchard trees etc., and the methods of spraying recommended. Formulas for fungicides, and insecticides are described.

A list is given of tropical fruits, spices and beverage plants in the Philippines, and Tables show the number of plants, set at given distances, required for 1 hectare and the general spacing according to the type of plant etc. Tables of common measures employed are also added.

The author has issued this publication in the hope that it will serve to popularise better methods of propagation, particularly asexual methods, and better methods of cultivation of superior varieties of tropical fruits

162 – **Selection of Stocks in Citrus Propagation.** — WEBBER H. J., in *Bulletin No. 317, College of Agriculture, Agricultural Experiment Station, Berkeley, California*, pp. 269-301, Figs 14. Berkeley, Jan., 1920.

The older methods of budding stock of different types and unknown character of growth are believed to be largely responsible for the different sizes of budded trees developed in the nursery, and also for many of the irregularities in size and fruitfulness of orchard trees. The author made comparative tests wich large, intermediate and small nursery trees, and emphasises the fact that although every care was taken at every step to reduce the amount of variation through using good sized stocks and buds from highly selected trees, nevertheless, when the buds were 2 years old and ready to transplant into the grove, they showed considerable variation in size. The great influence that the stock may cause on the scion is well illustrated by the growth of the Eureka lemon on trifoliate orange stocks as shown by trees grown at the Citrus Experiment Station.

At 13 years of age the buds on the latter stocks of which there were about 15, were not more than 1/5 the size of those on sweet, sour or grapefruit stock.

Some evidence may be drawn from the fact that the Chinese lemon and the Florida rough lemon which differ from each other much in the same way as the different types of sour orange, showed that the former proved a poor stock while the latter gave excellent results

From the results obtained in the authors' experiments the following recommendations are made: 1) the importance of growing and fruiting buds from the types and sizes which make up the composite mixture grown at present as sweet and sour orange stocks etc., 2) the severe culling of the seedlings at the time of transplanting from the seed bed the seed bed; 3) buds should never be inserted on inferior small stock. The larger nursery trees in the experiments described continued to show their decided superiority over the intermediate and small trees 4 1/2 years after budding and 2 1/2 after transplantation, 4) under sized buds should be cut out when the budded trees have reached the age for transplanting into the orchard. The number of trees which may have to be discarded will depend on the variation present in the nursery.

The importance of discarding carefully is evidenced by the fact that even when the stocks had been selected with much more care than ordinarily as in these trial experiments and the buds taken from good trees of known record, yet about 15 % of the Washington navel trees were discarted and a somewhat smaller percentage of the Valencias and grape fruits.

163 – **Bud Variations as the Cause of Deterioration of Old Fruit-tree Varieties.** — See No 148 of this *Review*

164 – **Ripening of Pears: Changes Taking Place During the Stages of Development and the Temperature Effects on Composition.** — See No 217 of this *Review*.

165 – **The Direct Hybrid Bearer "4401 de Couderc" in Portugal.** — DUARTE D'OLIVEIRA, in the *Revue de Viticulture*, Year 27, No 1378, pp 350-351 Paris, Nov, 1920

Results obtained in Portugal with the new direct hybrid bearer, 4401 de Couderc, which has taken some time to propagate. It was only in 1918 that a plantation of 2 or 3 branched cordons could be made.

Although the plantation is still so young, (in the second year), and in consequence the grapes are not very large, it has been possible to observe that the productivity of the vine is excellent and that it is absolutely resistent to mildew. The glucometric degree, acidity, and yield have still to be considered, all facts of great importance as regards a new vine This has been done by the author in comparison with *Pinot Noir* and *Cabernet Sauvignon* (French) and *Douzellinho do Castello* and *Alvarelhão* (Portugese). The following results were obtained:—

	Density et 15° C	Sugar por litre	Alcohol	Total acidity as Tartaric acid	Yield in juice per kg. in cc.
Pinot noir	1109	260	15.3	9.0	500
Cabernet Sauvignon . .	1084	194	11.0	8.3	542
Donzellinho do Castillo.	1107	255	15.0	11.0	540
Alvarelhão.	1077	175	10.3	12.0	702
4401 de Couderc . . .	1110	263	15.5	8 5	620

166 - **British Empire Forestry Conference.** — *Quarterly Journal of Forestry*, Vol. XIV, No. 4, pp 265-294 London, Oct, 1920.

The British Empire Forestry Conference, consisting of the delegates from the British Empire, assembled in London on July 12-21, 1920. After deliberation and discussion certain resolutions were passed which will be brought to the notice of the respective Governments. These may be summarized as follows.

I. *Forest Policy.* — In view of the great importance to the Empire as a whole, as well as to each of its component parts, of producing a sustained yield of all classes of timber, and of encouraging the most economical utilisation of timber and other forest products, and of maintaining and improving climatic conditions in the interests of agriculture and water supply, each of the Governments of the Empire should lay down a definite forest policy to be administered by a properly constituted and adequate forest service.

II. *Survey of Resources.* — The foundation of a stable forest policy for the Empire and for its component parts must be the collection, coordination and dissemination of facts as to the existing state of the forests and the current and prospective demands on them. (A note is appended descriptive of the Survey desired).

III. *Constitution and Status.* — In order to attain continuity in the development of forest resources it is desirable that certain elements of stability be secured in the constitution of the forest policy. This may be done by the following measures :

(1) The definition, where this has not been done already, of forest policy in a Forestry Act or Ordinance.

(2) The reservation, for the purpose of economic management and development of forest land, under conditions which prevent the alienation of any which is primarily suitable for forests, except for reasons consistent with the maintenance of the forest policy as a whole.

(3) The assurance to the Forest Authority of funds sufficient to carry out the accepted, policy for a series of years.

(4) The grant to members of the forestry service of the status of Civil Servants with due provision for pension.

(5) The appointment as the chief officers of the forestry service of persons having a high standard of training in forestry, their selection and promotion being by merit alone.

(6) The establishment in each of the larger parts of the Empire, and for the Colonies not possessing responsible government collectively, of an officer, or officers, having special duties of advising as to forest policy, and surveying its execution

IV. *Organisation of Forest Industries.* — Its is extremely desirable that the Forest Authority should be in close touch and consultation with organisations representing the interests concerned in the extraction and utilisation of timber and other forest products.

V. *Publicity.* — It is the duty of the Forest Authority in every part of the Empire to adopt and encourage methods of education and publicity in order that the people may be fully informed of the aims and purposes of forest policy and may thus be induced to co-operate towards its successful fulfilment.

VI. *Distribution of Forest Plants.* — The Conference have had brought to their attention the advantages which have accrued in several parts of the Empire from the wide distribution of forest plants, and desire to bring the method of encouraging tree-planting by distribution of plants either from Government or private nurseries gratuitously or at cost price to the earnest attention of their Governments.

VII. *Terminology and Trade Nomenclature.* — The following questions should be referred to the proposed Imperial Forestry Bureau immediately on its formation :— i) Standardisation of forest terminology ; ii) Correct identification of timbers, and standardisation of their trade names.

VIII. *Research.* — The scheme of research work is set out in a report from a Committee appointed to prepare a draft scheme for the organisation of that research work which is essential to the progress of forestry including both the production and utilisation of forest produce, the Committee to pay particular regard to the importance of avoiding overlapping and of co-operation with existing institutions. The report deals with the organisation and sub-division of research, with the relation of the different parts of research to one another and to education and practice, and with the subjects of research both generally and in relation to the needs of the different parts of the Empire. The report received the approval of the Conference and was recommended to their Governments for early consideration and approval.

IX. *Education.* — It should be a primary duty of Forest Authorities throughout the Empire to establish systematic schemes of forestry education. It has been found for climatic and other reasons that it would not be possible for each part of the Empire to establish a complete scheme of forestry education of its own, and therefore it is essential that those parts of the Empire which are willing and able to establish complete systems should, as far a possible, frame such schemes with a view to combining for meeting the needs of those parts which can themselves only make a partial provision for their requirements. Part of this subject has been dealt with by a committee, whose report, which refers mainly to the higher training of forest officers is approved by the Conference. The main principles embodied in this report are as follows :—

1) That one institution for training forest officers be established in the United Kingdom

2) That students be selected from graduates having taken honours in pure or natural science at any recognised University.

3) That it be an integral part of the work of the institution to arrange supplementary courses at suitable centres for students requiring special qualifications and also special courses for forest officers from any part of the Empire, whether at the institution itself or at centres of training in other parts of the world. The Governments should recognise these courses as part of the ordinary duties of the forest officer, at any time during their service, and the Governments concerned should give special facilities to forest officers in their service to attend such courses.

4) That a Department of Research into the formation, tending and protection of forests be associated with the training institution.

5) Encouragement should be given to the existing provision made by Universities and Colleges for forestry instruction for those who do not desire to take the full course suggested for the forestry service. It appears that this is especially applicable to the United Kingdom.

It is also desirable to make adequate provision for woodmen's schools for the training of foresters as distinct from those which are intended for forest officers.

X. *Forestry Bureau.* — The Conference approve the suggestions and recommendations for the constitution of an Imperial Forestry Bureau, and strongly urge upon their respective Governments that they should contribute to the support of the Bureau as therein suggested. They feel that it will be largely upon the work of such a Bureau that the proper development of the forestry resources of the Empire will depend and they therefore cannot over-emphasise its importance as a part of Empire organisation. The objets of the Bureau are defined as follows:—

1) To collect, co-ordinate and disseminate information as to — (*a*) Forest education, research, policy and administration; the constitution, organization, and management of forests; and matters arising out of or incidental to the growing of timber and other forest products; (*b*) The resources, utilisation, consumption and requirements of timber and other forest products.

2) To ascertain the scope of existing agencies with a view to avoiding unnecessary overlapping.

3) To devise means whereby existing agencies can, if necessary, be assisted and improved in the accomplishment of their respective tasks.

4) To supplement these agencies, if necessary, in order to obtain any information not now collected which may be required for the purposes of the Bureau.

5) To advise on the development of the forest resources of the Empire or of particular parts thereof, in order that such resources may be made available for the purposes of Imperial defence or of industry or of commerce (1).

XI. *Future Conferences.* — The Conference is convinced that the holding of Conference of Representatives of the Empire on forestry matters is of great service. They recommend that the next Conference be held in the year 1923 and that, if the Dominion Government approves, it be convened in Canada.

167 – **The Forest Resources of Spanish Morocco.** — *Iberica*, Year VI, No. 292, p. 131. Tortosa, 1919.

The eastern part of Morocco which is under Spanish influence is totally lacking in vegetation. The forest products are limited to firewood furnished by the brushwood which covers part of the mountains, especially those of the Quebdana chain, and Mounts Ameyer, Ziata, etc., and also to esparto (*Stipa tenacissima*), a textile plant which grows over 85 000 hectares of the mountains down to their lowest spurs, and which is now exploited. No true woods exist in the known part of the central region, where fuel is regularly obtained from the brush which grows at Cudia Taifor, on Mount Dersa and its spurs covered with lenticus, heather, and arbutus.

The "gabas" of Larache, Bu-Xaren, and Sahel in the western region can fairly be called woods. In the region of Alcazar there are scattered and unimportant groups of trees. The dominant species is the cork-oak, mingled with small olive, wild pear and oak trees. At Larache the gaba extends over 3 000 hectares, about half of which is covered by the cork oak; that at Bu-Xaren covers about 1500 hectares, moreo r less mingled with the cork oak.

That at Sahel covers about 7000 hectares, mingled with stands of oak and arbutus. This last area includes several villages and a great number of fields. In the gaba of Larache nearly all the cork-oaks have been stripped, the beneficial effect of which was observed from the beginning. In the gaba of Sahel parcelling out has been finished and the clearing of the brush and pruning of the cork-oaks is in hand.

The gaba of Bu-Xaren is not utilised to such an extent as that of Larache to which it is joined, the whole making a forest 6000 hectares in extent. The gathering of fuel wood from these gabas is practised tairy regularly, a revenue of about 13 000 pesetas per annum being obtained.

168 – **The True Mahoganies.** — Rolfe, R. H., in *Royal Botanic Gardens, Kew, Bulletin of Miscellaneous Information*, No. 4, pp. 201-207. London, 1919.

Of late years extensive planting of Mahogany trees has taken place in Trinidad and some other British colonies, and numerous specimens and fruits have been received at Kew with the enquiry as to whether they represent the true plant. Mahogany has long been known as the timber of a tree called botanically *Swietenia Mahagoni* Jacq., usually said to be a native of the West Indies and the adjacent coasts of Central America, but the term has also been extended to other red-brown timbers possessing somewhat similar properties, some of them belonging to other genera of Meliaceae and some to quite different families. The term, however, was originally applied to the West Indian tree, the timber of which has been known for upwards of 300 years, and under the name of Spanish mahogany, early became famous for the construction of articles of furniture.

At a somewhat later date British Honduras became famous as a source of mahogany, which until 1886 was generally regarded as the timber of *Swietenia Mahagoni*. In that year, however, Sir George King described and figured a new species under the name of *Swietenia macrophylla,* this having been grown in the Royal Botanic Gardens, Calcutta, from seeds collected in Honduras. Since then it has been generally recognised that Honduras mahogany is specifically different from the West Indian tree. There is also a third species, *S. humilis,* Tucc., a native of Western Mexico, which was thought to be in cultivation at Calcutta. Specimens of the Calcutta tree, however, including fruits, have recently been received at Kew, and prove to be a form of *S. Mahagoni,* Jacq. Further species formerly referred to *Swietenia* have now been transferred to other genera.

The present paper is limited to a description of the species of *Swietenia* proper, to which the true mahoganies belong.

169 - **Observations on the Planting of the Quicker Growing Conifers.** — Stewart, H. S., in *Transactions of the Royal Scottish Agricultural Society,* Vol. XXXIV, Pt. 2, pp. 141-145. Edinburgh, Nov. 1920.

The huge increase in the cost of plants and of labour, impels attention to the question of spacing, and the importance of ascertaining the best arrangement for various species of conifers in order to obtain the best silvicultural results at the earliest economic period.

The author carefully watched the effects of close planting on Japanese larch and Douglas Fir on a very favourable greensand soil and drew the following conclusions. Even the closest planting, at 3 feet, does not prevent, and only partially restrains branch growth, and if clean boles are required, hand pruning close to the stem must be utilized. The inadequacy of natural cleaning was evidently proved in two cases described.

Taking into consideration the question of root room, to obtain the greatest possible amount of cubic feet of such timber over a given area within a period of 15 to 18 years, which is the time required before these species acquire marketable value, the following scale of planting distances is advocated: —

For sitka spruce (pure) 5 ½ feet; for Japanese larch (pure) 6 feet; for Douglas fir (pure) 7 feet. The number of plants required per acre (square planting) respectively is 1440, 1210 and 889.

The author admits that this method of spacing will involve a certain amount of branch shortening in the earlier years etc., but the expense of these operations will not approach the cost of the initial planting of much greater quantities of young plants per acre. It seems clear that what may be reasonably close for ordinary conifers is unreasonably and even disastrously close for the quicker growing kinds.

170 - **The Establishment of a Douglas Fir (*Pseudotsuga taxifolia*) Forest.** — Hofmann, J. V. (U. S Forest Service), in *Ecology* (1), Vol. 1, No. 1. pp. 49-53, figs 1. Brooklyn, N. Y., Jan., 1920.

The varied combination of characteristics give the Douglas Fir (*Pseudotsuga taxifolia*) a wide range of adaptation, and a resultant superiority over its associates. The measurable characteristics which give it such a prominent place in a formation where the red cedar (*Thuja plicata*) and the western hemlock (*Tsuga heterophylla*) comprise the climax forest may be briefly stated thus:— The production of heavy crops of seed which is an evident advantage as this seed is a favorite food of the indigenous rodents. The surplus produced over the amount consumed by rodents is large and is stored away by them in the débris and mineral soil beneath the trees in " caches " varying in size from a few seeds to bushels of cones. But before the following spring all traces of the rodents' work have been eliminated by the snow and rain. The seeds are thus preserved in their natural storage of cool temperature and moisture conditions which reduce the oxygen content of the soil. Experimental evidence has proved the seed to be viable after 6 years storage in this manner, but it may lie a longer period of indefinite length. When the forest is removed by fire or by cutting, the stored seed is left under favourable germination conditions and immediately responds to the stimuli. The same holds true of the Western White Pine, (*Pinus monticola*). With the Douglas Fir, the early and quick germination of the seed under favourable conditions and the rapid development of a long radicle so pronounced compared with hemlock and cedar, enables it to become established where the others fail.

---

(1) *Foreword.* — This Journal is issued to meet the demand for the collective publication of articles on ecology. Its pages are open to all who have material of ecological interest from whatever field of biology. While the variety of fields may cause diversity of treatment,

The unfavourable factors are the inability to withstand shade,which results in a reduced possibility in reproduction under a forest canopy. This is the underlying factor which makes the Douglas Fir a one generation tree in a natural cycle of this formation, and results in a consequent elimination from the climax forest.

These observations were made in the Pacific North west region of America with a view to pointing out that the above-mentioned factors are within the control of man, and it is on them that the scientific management of Douglas Fir must be based in order to keep the said region under continuous natural production of this most important species.

171 - **Mechanical Timber-Felling.** — GERDIL, H. (Inspecteur des Eaux et Forets), in the *Bulletin officiel de la Direction des Recherches scientifiques et Industrielles et des Inventions* reproduced in *Le Bois*, Year 30, Nos. 28 and 29. Paris, Dec. 9 and 16, 1920.

Timber-felling by hand is now a very costly and slow process, owing to the high cost of manual labour. This article supplies the latest information regarding the mechanical felling of timber in France, a problem which assumed great importance during the war.

Each successive operation, clearing, cutting both small and large wood, trimming, and logging, requires, according to the author, a special machine.

Trials of felling with red-hot wires have been discontinued in prac-

---

yet the ecological significance of the papers will make them of general interest. Specialisation is inevitable, but makes more urgent the need for co-operation. To approach different subjects from similar points of view is to lay the foundations of co-operation.

tice, not only becase this method of carbonisation is too slow but there is too great a risk of killing the stumps and so ruining the coppices. The patent process of H. GANTKE, whereby a moving red-hot steel wire is employed was also tried, but the author thinks that the best way is to use a cutting tool.

The author briefly describes the instruments which were tested and found satisfactory; these were the alternating saw, circular saw, endless band-saw, mechanical axe or chisel, the wire or chain friction saw, the multiboring machine.

The problem of clearing has been solved by small locomobile saws several types of which are described by the author.

Credit must be given to the Americans who have produced a single machine which will carry out the whole work, with the help of a single workman.

172 – **The Use of Tanks in Sylviculture.** — HICKEL, R, in the *Comptes rendus de l'Académie d'Agriculture de France*, Vol. VI, No 38, p. 905. Paris, Dec., 15, 1920.

M. Laurent RAYBAUD, preparateur de botanique à la Faculté des Sciences de Marseille, has suggested the use of tanks in the forests as fire-fighters, in re-afforestation, and for maintaining the fire-trenches.

In this last capacity, two tanks will be used, one on each side of the trench, dragging a harrow which will pull up all the weeds and throw them into the bottom of the trench, where they will afterwards be set on fire by flame-throwers provided with the tanks. The tanks will also carry a water tank, so that the upper edges of the trenches can be watered if there is any risk of the fire spreading in the forest.

LIVESTOCK AND BREEDING

173 – **The Persistence or Disappearance of the Virulence of Aphthic Milk During the Manipulations Subsequent to Milking.** — LEBAILLY, C., in the *Comptes rendus de de l'Académie des Sciences*, Vol. 171, No. 21, p. 1029. Paris, November, 22, 1920.

The author has shown (1) that the virulent nature of the milk is one of the earliest symptoms of aphthic fever, and that if given to young animals (calves and pigs) it causes their death from an acute form of the disease. On many farms, this mortality among the young stock has amounted to 100 %.

Certain breeders drew the author's attention to the fact that, formerly, on the same farms, epidemics of aphthic fever did not result in so many victims, and they were inclined to think that some other cause of contagion was at work. In the course of his enquiries, the author recognised the truth of this remark, and he believes, that he has discovered why formerly, cases of rapid death were much less frequent.

Now-a-days, the skim milk is given to the animals as soon as it leaves the separators, whereas, until recently, it was collected after the cream had risen, which is always attended by the beginning of lactic fermentation. Under these conditions, the aphthic virus, which is very easily affected, becomes greatly attenuated, if not completely destroyed. The course of the present out-break is being carefully watched, so that the epidemic affords all the advantages of a large-scale experiment. On small farms, where mechanical separators have not been introduced, the young stock fed on milk in which lactic fermentation had commenced, were either immune throughout the epidemic, or contracted the disease in a mild form. The centralisation of the milk in large dairies, and the division of the skim milk, has had the opposite result, and led to the rapid spread of aphthic fever. This consequence could not be foreseen, as it was not known that the milk of apparently healthy animals which are in the incubation period of aphthic fever, is a source of infection.

174 - **The Dipping of Sheep in So-Called Carbolic Dips.** — STEAD, A (Research Chemist, Grootfontein School of Agriculture, Middleburg. Cape), in the *Journal of the Department of Agriculture, Union of South Africa*, Vol. I, No. 6, pp 536-547. Pretoria, September, 1920.

The object of this paper is to warn both sheep farmers and dip proprietors that, while these so called dips are safe with some waters, they are unsafe with others. The most dangerous water appears to be of the moderately hard type, becase the oily globules separated under these conditions are very small and easily overlooked.

Investigations were carried out with three different coal tar dips. In the first case, (mixture and water in the proportion 1 : 50), of the first lot of 12 dipped, 6 died; of the second lot of 21 dipped, 5 died; of the third lot of 35 dipped, none died. Examination of the dip showed that it did not contain arsenic, that true phenol was practically absent, but that it contained higher phenols, pyridine, hydrocarbons, soda and water. It was not found possible to obtain a true emulsion by mixing with either fountain or distilled water; but distilled water mixtures contained very much less separated oils than the fountain water mixtures. The most perfect emulsion was obtained by boiling the distilled water before mixing, the explanation being that boiling expelled dissolved carbon dioxide from the water. A slightly improved emulsion was obtained with fountain water by placing it in a vacuum chamber (to remove carbon-dioxide) before mixing. An equally good result was obtained as that made with unboiled distilled water, by softening the water with soap prior to mixing, and also by partially softening the water prior to use by boiling.

The author's conclusion is that the first sheep dipped took with them out of the tank, not a chill, as was suggested, but separated oils.; that they were, in effect, dipped in too strong solution. The fact that all the sheep were not affected in a similar way may be attributed to the fact that the separation of oils was not found to be an instantaneous process and that some sheep were more resistant than others.

In the second and third cases, the results of the dipping were of a similar nature to the first, and bear out this point.

Recommendations. — 1) To free the dip wash of its separated oils by drawing absorbent material through it; 2) To soften the water before using, or by adding more soap to the concentrated dip; 3) To use small tanks; 4) To wash the animals well with a solution of Epsom salts and water; a hypodermic injection of a watery solution of Glauber salts is also advised.

The most reliable test, probably for the separation of dip oils, in doubtful cases, is to prepare some of the dip wash and pour it through a piece of blotting or filter paper folded to fit a funnel. Some at least of the separated oils should be retained by the paper. The risk that sometimes attends the dipping of sheep in these fluids has also been noted in America (1).

A note is added on the physiological action of carbolic acid by FOURIE (*Lecturer in Veterinary Science, Grootfontein School of Agriculture*).

175 - **Observation on the Body Temperature of Dry Cows.** — KRISS, M. (Institute of Animal Nutrition, Pennsylvania State College), in *Proceedings of the National Academy of Sciences of the United States of America*, Vol 6, No 8, pp 539-541. Washington, D C., Sept, 1920

An attempt was made to secure data regarding the extent and the course of the body temperature variations in cattle, and to study some of the factors that might influence them. The investigation covers a period of some 16 weeks. The animals were two dry cows used at the same time for metabolism experiments with the respiration calorimeter, in which strict control of feeding, environment etc. is maintained.

The observations on the thermal gradient were made at a depth of 4 to 7 inches, and all others at 7 inches depth. Results may be summarised as follows: 1) The rectal temperature was higher than the vaginal when measured at the same depth of 7 inches, showing, an average excess of about 3°F. The relative values, however, varied under different conditions, but showed a trend towards parallelism; 2) A fall in body temperature invariably followed the drinking of water, varying according to quantity drunk. After the effect of the water drunk in the morning had been overcome, the temperature remained fairly constant till about 2.30 p. m., otherwise it was practically constant the entire morning. From 2.30 until 5 p. m., there was a gradual rise in temperature; 4) Eating of feed raised the body temperature slightly for about half an hour when the cows received a maintenance ration; 5) A comparison between the temperatures taken at varying depths showed the unreliability of measurements at a depth of less than 6 inches; 6) The standing as compare with the lying position of the animal, had hardly any effect on the body temperature; 7) there was no difference in the temperature when measured before or after defecation; 8) daily fluctuations depend to a greater extent on the individuality of the cow; 9) a variation of 8°F in the rectal temperature of the same animal was observed, when measured at the same hour of the day under identical conditions and outside the influence of water or feed; while under the influence of water a difference of 1.3°F was observed at the same hour on two consecutive days.

176 – The Influence of Dry versus Fresh Green Plant Tissue on Metabolism. — I. Forbes, E. B., (Ohio Agricultural Experiment Station The influence of Fresh Food in Lactation, in *Science*, Vol. LII, No. 1350, pp 467-468, Nov., 12, 1920. — II. Robb, E. F. (University of Minnesota) Influence of Dry versus Fresh Green Plant Tissue on Calcium Metabolism, in *Science*, Vol. LII, No. 1352, pp. 510 New York, Nov., 26, 1920.

I. — A report of experiments with cows carried out in the department of Dairy Husbandry at the Ohio Experimental Station. Since 1911. a Group of Holstein-Fresian cows were maintained on dry feeds and silage alone. No green feed was allowed. Several of the animals now in the group were born in it, and had reached maturity entirely without green feed.

The said cows grew to normal weight, and produced and reared calves without marked or certain irregularity, or abnormality. The milk production was fair only, it being obvious that with normal treatment these cows would have given more milk. They were easily forced off feed and were noticeably in a less thrifty condition, as indicated by flesh and coats, than the balance of the herd, which went to pasture.

During the past summer, the author conducted palatability tests on these cows, with various mineral supplements, consisting of various calcium phosphate and carbonate preparations, fed alone or mixed with common salt. The cows showed a keen desire for such feeds, having eaten in several short periods, from approximately $^3/_4$ lb. to more than 1 ¼ lb. of mineral supplement per head per day. The avidity with which steamed bone was eaten, considered in connection with the discovery that negative calcium balances normally prevail during lactation in cows on dry feed, and the conclusion of Hart, Steenbock and Hoppert, that fresh grass favourably affects calcium retention, suggests that these dry-fed cows are in a state of mineral depletion, especially while giving milk. This suggestion appears therefore, to be a matter of practical importance in connection with milk production, but rations of dry feeds and silage though probably deficient in some constituent, are not entirely lacking in any essential.

II. — In order to make more exact studies of calcium metabolism on guinea pigs a group was fed with calcium free diets during and for 2 days before metabolism periods of 3 days in length. This made it possible to draw definite and reliable conclusions. The animals were under starvation conditions as regards calcium, but this lasted only 5 days, and examination of their bones did not show any difference compared with animals fed with liberal amounts of calcium. Animals that had been on diet of dried plants 14 days before the experiment, eliminated twice as much calcium as those fed on fresh green plants, and which during the experiment had received calcium-free orange juice. With animals that had been 21 days on a dry diet, the difference compared with the controls was more striking. Scurvy appeared in all the animals on the dry diet.

The author therefore points out that the antiscorbutic vitamine appears to be greatly reduced by drying (except in very acid foods *e. g.* fruits). The marrow tissue of the bones increases in proportion to the real bone and calcium is apparently lost from the bones in this way. This contradicts the idea presented by HART, STEENBOCK and HOPPERT, that the loss of calcium with dry feed is connected with rickets or an antirachitic vitamine.

177 - **Fodder Values for Milk Recording Societies and Dairy Herds.** — STEWART, D W, in *The Scottish Journal of Agriculture*, Vol 3, No 4, pp 433-438. Edinburgh Oct. 1920.

A report of the Scandinavian method of calculating fodder values. In Sweden an average sample of barley is taken as the standard, therefore if 1 lb. of average barley is taken as the fodder unit, then the unit of any other food will be that weight of it which will give the same result as 1 lb. of barley fed to a cow in a properly balanced ration. The milk producing value of 100 lb. of barley is 75 lb. The starch equivalent is 72 lb. Hence, if a unit is chosen for the fattening of cattle or the feeding of pigs instead of milch cows, the standard would be estimated on a similar basis to that described above.

A comparison between the average Scandinavian analyses and those made in Great Britain shows little difference. There is, however, a difference in the composition of homegrown fodders in Norway as compared with mid or southern Sweden; the former possessing a higher fodder value.

The cows in the byres are divided into two groups according to whether they are nearly dry or are low yielding, medium or high yielding. Rations are calculated for each group, and the individual animals receive the same amount of food daily. A cow moves from a higher to a lower group as her yield decreases. The rations are calculated as follows: —

Maintenance Ration. — For a 9 cwt., cow allow $6\,^2/_3$ units daily. For each 1 cwt. above (or below) 9 cwt., add (or subtract) .5 units. For each unit, allow .1 lb. of digestible proteid. These figures represent the bare maintenance requirements of dry barren cows: but in-calf cows are allowed 50 % above these quantities.

Production Ration, (in addition to above ration). — Allow 3.33 units for each 10 lb. of average milk (3.5 % fat), yielded daily. This applies to Ayrshire, Shorthorn or Holstein cows, but 3.86 units per 10 lb. milk should be allowed for Jersey and Guernsey cows. (4.5 % fat).

The cakes and meals mixture is worked out in the same way. It might consist of 3lb. barley bran, 3 lb. dried grains, 2 lb. sesame cake, and 2 lb. decorticated nut cake, or in that proportion. Of this mixture 1.02 lb. is a fodder unit, and this contains .207 lb. digestible proteid.

In the keeping of fodder records the allowance for pasture may appear to present a difficulty. If, however, cows are fed according to their live weights and milk yields this difficulty may be overcome.

The results obtained in 10 years successful work by one of the Scandinavian control unions, showed that in the tenth year 165.9 lb. of milk, or an equivalent 5.7 lb. of butter, was produced from 100 fodder units as compared with 120.8 or 4.13 for the first year, and 152.2 or 5.08 for the fifth year.

The feeding standards for other cattle are recorded as follows: —

Per Day per Head.

Young Dairy Cattle	Live Weight	Per Day per Head	
		Fodder Units	Digestible Proteid
	lb.		lb.
2–3 months	154	4 6	0.55
3–4 »	220	5 9	0 70
4–6 »	352	7 5	0 88
6–12 »	484	8.4	0 92
12–18 »	660	9 2	0 99
18–24 »	880	9 7	1 06
Over 24 »	090	9 9	1.09
Fattening cattle			
1–2 years	880	17.6	1.76
Adult	1 100	22.0	1.65
Cows	1 100	22.0	2.75

By means of fodder records of each cow it is possible to see which of them pay for their keep. It will be necessary to weight up the food used by each animal during a whole day about 20 times in the year. The food actually consumed on the control day represents the average consumption during the 10 preceding and the 10 following days. By multiplying the fodder of the control day by the days in the period, the amount of food used is thus estimated.

Marked progress has been made by the aforementioned control unions as the result of scientific breeding to get higher milk yields without lowering the proportion of fat in the milk.

A typical fodder table is given showing the average and variation to 1 fodder unit, and the digestible proteid per unit. The author states that his article is based on the publications of Prof. NILS HANSSON: — "*Handbok i Utfodringslära*" and "*Kontrollföreningarnas Arbetsfält*", published by C. E. FRITZE, Stockholm.

178 - **Lupins as a Livestock Feed.** — See No. 119 of this *Review*.

179 - **Press Cake of the Cohune Nut (*Attalea Cohune*).** — See No. 120 of this *Review*.

180 - **Crosses Between Ewe and He-Goat, Between Goat and Ram and Between Sow and Wild Boar in Sardinia.** — GALBI SERA, S., in *La Clinica veterinaria*, Year XLIII, Nos. 21-22, pp. 585-586. Milan, November, 15, 1920.

Crosses between the sheep and he-goat, and between the goat and ram were made in ancient times. The Romans gave the names of *tisiri* to the offspring of the first cross, and of *musmone* to that of the second.

Several stock breeders have tried to repeat these experiments, but without success, although the existence of such hybrids has been reported more than once (1).

The author has often observed the offspring of he-goat × sheep in Sardinia ; these animals in bulk, udders, and wool combine the characters of both parents. The female hybrids are preferred to sheep, on account of their larger milk yield. In order to obtain such crosses, it is necessary for the he-goat to have been brought up from a kid among the sheep. The hybrids are interfertile, but re-acquire the sheep characters.

In Gallura, the ram and goat are frequently mated ; the offspring resemble the goat in shape and coat, the only difference consisting in the size of the ears, which are shorter and wider than those of kids, and are carried like the ears of lambs.

Sow × wild-boar hybrids are very common, especially at the times when the herds of swine are sent into the oak-forest, where they lead a wild life. As a rule the offspring have a spotted coat, and show certain characters that do not belong to domestic animals.

Sometimes, the sow produces a litter composed half of young pigs and half of young wild boar, in which case, the latter separate from the former, and lead their own lives.

181 - **The Indices of the Mule.** — PORCHEREL, A., in *Revue vétérinaire*, Vol. LXXII, Third Series, Vol. 1, pp. 746-755. Toulouse, December, 1920.

The author has given the dimensions of the various parts of the mule's body and limbs (2); The ratios between some of these measurements give indices that, in certain cases, can supply information regarding the morphology of the animals.

I. TOTAL CEPHALIC INDEX (relation between the maximum width of the head and its length calculated as 100). This index varies between 38,3 and 43.3 in the mule, and between 35.7 and 56.09 in the ass. The lowest indices are usually found in the case of mules coming from America. The total cephalic index of the African donkey is larger than that of the Poitou donkey.

No conclusions can be drawn from this index as to the transmission of the cephalic characters of either donkey or horse.

The mule appears to be intermediate between these two animals ; very numerous variations, however occur, owing to the transmission of the hereditary characters of both horse and donkey which show themselves in the hybrids.

II. BODY INDEX (relation between scapular-ischial length and circumference of thorax, the latter calculated as 100). — In the case of the mule, the author obtained figures varying between 83 and 98, in that of the donkey between 80 and 93. There is no connection between the body index and the origin of the animals. In pack-mules, the best indices vary from 83 to 88, and indicate those that are most satisfactory for carrying loads.

---

(1) See *R*, 1918, Nos 889 and 1140. (*Ed*)

(2) See *R.*, Oct 1920, No 1010. (*Ed*)

III. THORACIC INDEX (relation between the greatest width and the greatest depth of the chest). — In most mules, the chest is usually more elliptical and the ribs are less rounded than in the horse The author has observed variations between 83.6 and 90.5.

IV. INDEX OF COMPACTNESS (relation between the weight of the animal and the number of centimetres in height above one metre). — The figures obtained vary between 6.5 and 9.7.

In the case of pack-mules, this index should vary between 8.5 and 9.5, which shows a good proportion between the height and the weight of the animal.

V. DACTYLO-THORACIC INDEX (relation between the circumference of the cannon-bone and the perimeter of the thorax). — This in the mules measured by the author, varied between 0.096 and 0.121. The best measurement indicates that the circumference of the chest is 8 or 9 times that of the cannon-bone.

In addition to the height, the weight of the animal must be taken into account, as a limb cannot be pronounced stout or slender except in proportion to the weight of the body it is called upon to support. In order to determine which mules of equal weight had the strongest legs, the author found the circumference of the cannon-bone per 100 kg. of weight.

The lowest figure was given by a Corsican mule (3.75), the highest by a mule of American origin (5.31) ; the average was 4.44.

In the case of the donkey, he found an average weight of 177 kg., the average circumference of cannon-bone 0.143 m., and the circumference per 100 kg., 8.90 m.

There is thus no connection between the circumference of the cannon-bone, and the load the animal can carry

BARON's formula $95 \frac{C^2}{H} =$ load the animal can carry (C being the circumference of chest and H. the height at the withers), is therefore not always practically applicable. With this formula, too heavy a burden is obtained ; in the authors' opinion, it can be estimated more accurately at between $^1/_2$ and $^2/_5$ of the live weight. The figures thus obtained are lower, but in this case again, there is no connection between the volume of the cannon-bone and the theoretical load the animal can carry.

182 - **The Effect of Drugs on Milk and Fat Production** (1). — HAYS, F. A and THOMAS, M. G. (Delaware Agricultural Experiment Station), in the *Journal of Agricultural Research*, Vol. XIX. No 3, pp. 123-138, figs 8. Washington, D C., May 1, 1920.

The opinion that milk production and butterfat yield can be influenced by the use of drugs is widespread among dairymen. The objects of the author's experiments were: 1) To determine the effect of various drugs on the butter fat test of milking cows; 2) to study the effect on the total fat yield of producing cows: 3) to determine whether drugs have an effect on the health or on total milk production. The 4 cows of mature age selected for experimental purposes included one grade Holstein, one pure-bred Holstein, and two purebred Guernseys. The interval of experimentation with each drug was 5 days. The control and experimental periods alternated, and the order in which the drugs were given was so arranged that each cow received of the 8 drugs for a 5 day period. The cows were milked twice daily, the weight of milk recorded, and composite samples from each cow were tested for butterfat daily.

---

(1) See *R.* July Sept. 1919, No. 946. (*Ed.*)

The following table gives a summary of the results obtained:

Drugs used	Average total milk			Fat test			Average total butter fat		
	Control	Treated	Gain or loss	Control	Treated	Gain or loss	Control	Treated	Gain or loss
	lb.	lb.	lb.	%	%	%	lb.	lb.	lb.
* Food Tonic No. 1.	92.2	93.7	+ 1.5	4.37	4.57	+ 0.20	3.998	4.285	+ 0.287
Air slaked lime . .	67.3	81.9	+ 14.6	5.21	5.00	— 0.21	3.509	4.095	+ 0.586
Fowler's solution of arsenic	107.3	109.0	+ 1.7	3.72	3.86	+ 0.14	3.995	4.210	+ 0.215
Gentian.	113.5	108.2	— 5.3	3.93	3.98	+ 0.05	4.459	4.302	— 0.157
* German tonic mixture	108.8	108.0	— 0.8	3.97	3.75	— 0.22	4.205	4.049	— 0.156
Physostigmine sulphate	108.7	99.9	— 8.8	3.89	3.60	— 0.29	4.226	3.706	— 0.520
Sodium bicarbonate	93.1	90.8	+ 2.3	4.43	4.43	+ 0.00	4.132	4.020	— 0.112
Ginger	92.5	93.8	+ 1.3	4.28	4.32	+ 0.04	3.968	4.055	+ 0.087

* Food Tonic — 100 lb, oil meal, 5 lb., saltpetre, 5 lb, Epsom salts, 5 lb., gentian, 5 lb., fenugrek, 8 lb., powdered charcoal, and 5 lb., sulphur.

** Tonic mixture — 3 oz., black sulphide of antimony, 1½ oz, sulphur, 5 oz., each of fennel, caraway and juniper berries, 1 lb. common salt.

A study of individual records and average records does not indicate that drugs have a very pronounced effect on the production of the dairy cow. Air-slaked lime, however, fed in 2 oz., doses daily, may possibly increase milk production and total fat yield, but no other drug or mixture tested proved to be of any marked value. Results do not indicate that the difference in character of milk of Holstein and Guernsey cows, has any relation to their manner of reaction to drugs.

183 – **Winter Feeds for Ewes.** — ARKELL, P., in *Farm and Dairy*, Vol. XXXIX, No. 49, p. 1322. Toronto, Ont., Dec. 9, 1920.

The best feeds recommended for breeding ewes are swede turnips or mangels, good clover hay (preferably alfalfa), oats and a little bran mixed. The author feeds hay in the morning followed by roots, and roots first at night. For 1 doz. ewes, ½ bus. of turnips, 1 bus. of cut hay, and 12 qts. of grain as a midday feed, and hay and roots at night, would be good feeding and the flock should give good results. It is advised to give plenty of water also. Male animals should never be fed on mangels, as disease invariably sets in.

184 – **Pig Feeding and the Cost of Pork Production.** — RUSTON, A. G. (Lecturer in Farm Economics, Leeds University), in *The Journal of the Ministry of Agriculture*, Vol XXVII, No 4, pp 340-349 London, July, 1920

The great reduction in the number of pigs kept from 1915 onwards, in England, can most probably be accounted for by the increasing difficulty in securing food supplies for them, and by the widely prevalent idea that the high prices of pig meal and miller's offals made the production of pork economically unsound. Now that feeding stuffs are more readily obtainable, and prices have fallen, it was thought by the author that the actual detailed records of the receipts and expenditure in connection with the management of pigs on a Yorkshire farm of just over 300 acres, 1918-1919, might be of interest. The Department of Agriculture of Leeds University has for some time past been engaged in investigations into the cost of production of milk, pork, beef, mutton, crops etc. on a number of farms throughout the country, including its own experimental farm. On these farms, detailed valuations of the live and dead stock are made at the beginning and end of each financial year.

On the farm in question, the accounts for 1918-19 show a net profit of £414.19*s* 5*d* ; on the total capital outlay of £1,173.0*s* 8*d* the percentage profit would therefore be 35 ½ %.

Although there was nothing very radically wrong with the method of feeding the pigs, it does not follow that the best or most economical method had been adopted. The average ration fed to the pigs during the year, adhered to the standards suggested by KELLNER fairly closely. The average live weight per pig on the farm, throughout the whole year would be approximately 150 lb. According to this, the daily ration actually contained:

26 lb of dry matter per 1000 lb live weight
4 lb of digestible protein per 1000 lb live weight
19 lb of digestible starch equivalent per 1000 lb live weight

If 4 acres of grass, at an approximate cost of £10, and the produce from 1 ½ acres of vetches, at approximately £12, had been placed at the disposal of the pigs, it is probable that a saving of at least 3 tons of meal at £20 per ton might have been effected.

The author gives details of the cost of labour, food, rent and rates in addition to the Profit and Loss sheet. The importance of increasing to as large an extent as possible, the production of cheap home grown foods, is emphasised, if pork is to be produced on the most economical basis, and the results in the farm described, show that the breeding and rearing of pigs can be done now on economically sound and certainly remunerative lines.

185 – **Report on the Fifth, Sixth, Seventh, and Eighth Victorian Egg-laying Competitions** (1) **1915-1919** — HART, A., (Chief Poultry Expert), in *The Journal of the Department of Agriculture of Victoria*, Vols. XIV to XVII, pp 6. Melbourne, June 1916-19.

The Egg laying competitions started in Victoria 1904-1905 at the Dookye Agricultural College. Then, six White Leghorns won the test with 1313 eggs for 12 months. In the test concluded at Burnley in 1916, the winning pen produced 1661 eggs, in 1917, 1503 eggs, in 1918, 1405 eggs for 11 months only and in 1919, 1511 eggs ditto. These results are with light breeds in the wet mash section. Each year the White Leghorns were very much in the majority in the light breed tests. Figures indicate similar comparative results with this breed in the dry mash section.

---

(1) For fourth report of Competition, see *R.* Sept 1915, No. 915. (*Ed*)

With the heavy breeds, Black Orpington invariably took the leading place. Wet mash section :— 1915-16 total eggs = 1,507 ; 1916-17, 1409 (12 months) ; 1917-18, 1274 ; 1918-19, 1306 (11 months).

In Competition 7, the most interesting result was the Black Orpington hen which laid 307 eggs in 11 months. the highest result on record.

In Competition 8, no records were achieved, but the general results were satisfactory. The only other Light breeds besides White Leghorn taking part were Ancona, and Minorca, the first showing the best results. With heavy breeds other than Black Orpington, the Rhode Island Reds were the best, and showed superiority to the Silver Wyandottes and Buff Plymouth Rock, competitors in 1917-18.

The author gives details of the feeding and housing of poultry, and in the Journal 1919 suggest the advantage of a Co-operative Poultry Farmers Society to ensure success in the poultry industry and obviate difficulties in egg transport, etc.

186 – **A New Brazilian Breed of Fowl : The "Musica".** — DE CARVALHO, D , in *Chacaras e Quintaes*, Vol XXXII, No. 4, pp. 275-276 + 1 fig São Paulo, Oct., 15, 1920.

At Barra de Paraopeba (Western part of the State of Minas), there exists a breed of fowl which is distinguished by its peculilar crow, whence the local name of "Música" or "musicians" which according to the author, suits them but little. They appear to be a pure breed, which has been neglected and is now degenerate.

The plumage has always 2 colours : yellow tipped with black, or black more or less speckled with white. The hens are the same colour as the cock, but are less brilliant. Moreover, the dorsal region is very inclined and forms an acute angle with the tail. In both sexes the tarsi are a green that is almost black ; the small lobes are white and very regular ; on the crest is found a rudimentary tuft ; the crest is simple, evenly dentate and upright. The flesh is white and the skeleton slender.

The cock is the same size as the common hen but is of very different appearance. The tail is long, curved, and carried well, and gives him a very elegant appearance.

The author has undertaken the selection of this hardy and vigorous breed, because its characters are of practical value, neglecting however, the character from which it takes its name as it has no agricultural value.

187 – **Wintering Bees in Canada** (1). — SLADEN, F. W L. (Dominion Apiarist), in *Bulletin No. 43, Dominion of Canada, Department of Agriculture, Dominion Experimental Farms*, pp 3-12. Ottawa, 1920.

The author explains in detail the reasons why successful wintering depends chiefly on three conditions, namely ; the need of populous colonies consisting mainly of young bees, plenty of wholesome stores in the combs, and adequate protection from the cold.

---

(1) See *R.* June 1918, No 670. *(Ed.)*

The two ways of protecting bees are compared, i. e. 1) out of doors in cases filled with packing material, and 2) in doors in the cellar. The first method is found preferable in comparatively mild districts, and the latter in colder areas.

I. — The best and most economical type of wintering cases is found to be one made to take four hives *en lloc* and usually back to back. This method encourages warmth., and uses less material per colony, in construction. The case should be at least large enough to allow 4 inches of packing between the hives, and the sides and bottom of the case, as well as a space of 8-10 inches between the hives and the cover to serve as a air chamber. The sides and floor of the case should be of grooved and tongued boards, and the roof should be of thin boards nailed to a strong frame in telescope form, and covered with roofing to make it waterproof. A collapsible case is found to be convenient.

The construction of the flight holes needs particular attention and they should be cut in the sides of the case opposite the hive entrance, but a least 1 foot apart, To meet both winter and spring conditions the author advises the cutting of the hole 4 to 5 inches wide by 1 inch high, and to have a close-fitting piece of wood revolving on a screw which will reduce it to 1 inch by $^3/_8$ inch, or $^3/_8$ by $^3/_8$ of an inch. There should be no projecting ledge beneath the winter entrance to lodge snow and ice.

In a cold region, it has been found advisable, in placing the hives in the case, to leave a board or oilcloth covering over the combs to prevent the escape of too much heat and moisture. By placing sticks underneath, a passage is made for the bees to pass over the combs, and should be at least $^5/_8$ inch deep to prevent the blocking of the hive entrance and flight holes with dead bees in winter.

The packing should be well air spaced, and the process carried out in September, preferably before the fall feeding is done, and the bees ought not to be removed from the cases until late spring.

Experiments covering seven years at Ottawa, have shown that colonies wintered outside in the 4-colony cases, began breeding earlier and averaged stronger by the end of May, than those wintered in the cellar, but careful preparations were essential to ensure success.

II. — For a good bee cellar, the temperature keeps steady between 45° and 50°*F*, the air is fairly dry, and not without ventilation, and light is excluded.

The cellar should therefore be low in the ground and thus very little affected by changes in the outside temperature, and the ground should be well drained.

As to the time to bring the bees into the cellar, the best time advised is as soon after the last good flight as possible. In many places this is early in November. The best date to bring them out is usually when the willows come into bloom, if the weather is favourable.

A brief survey is given as to spring management.

188 – **Japanese Bivoltines in Italy.** — ACQUA, C. (R. Scuola Superiore di Agricoltura in Portici), in *Informazioni seriche*, Year VII, No. 20, pp.301-303 Rome, Oct., 20, 1920

Numerous second rearings of Japanese bivoltine breeds imported 3 years previously were carried out in 1920 in various parts of Italy. From observations made by the author in many sericultural establishments, according to rearings made at the Higher Agricultural school at Portici, it can be said that, save for certain percentage of failures, which were always normal in all the rearings even in spring, the Japanese bivoltine breeds of silkworms, and especially the "Nipponshiki" breed, which was preferred to the others, have given very satisfactory results; they have proved very resistant to high summer temperatures, and the cocoons have given a very good yield on winding. These results were observed particularly in those localities where the seed was promptly distributed and had not to suffer during the period of embryonic development.

In the Osimo district (Province of Ancona) where 120 oz. was produced and distributed by a local establishment, there were only 3 or 4 failures, although the temperature frequently rose above 30 C°.

Crossing between female bivoltines and golden males also gave satisfactory results, but the resistance to great summer heat was slightly decreased.

According to the author, and contrary to the opinion of CAMPBELL (1), the problem of second rearings in Italy may be solved if the following precautions are taken.

1) Establishments that prepare summer and early-autumn grain should really use these breeds, and abandon the system of distributing the seed of common annual breeds, which have generally proved to be unsuited to these special rearings.

2) The preparation of bivoltine "seed" should be made according to rule this being especially important because of the frequent phenomenon of false bivoltinism.

3) The breeders should take the greatest care especially during the first stages when, because of the rapid drying up of the leaves during the great heat of summer the young worms which lie hidden under the leaves are easily lost. The breeder does not see them and consequently after rearing, he is astonished to find so few worms and consequently, so few cocoons, although there has been no disease.

In any case, it should not be expected that the yield obtained in summer is as great as in spring; the average weight of the cocoons produced per ounce is always much less in summer, and the consumption of leaves is also less

---

(1) See *R.*, Nov-Dec, 1920, No 1166. *(Ed.)*

189 - **Cultivation of Eri Silkworms.** — JARDINE, N. K. (Inspector of Plant Pests and Diseases, Entomological), in *The Tropical Agriculturist*, Vol LV, No. 4, pp 247-249. Peradeniya, Ceylon, Oct, 1920.

The production of Eri silk (1) is more in favour in Ceylon than mulberry silk. The worm is fed on the leaves of the castor oil plant (*Ricinus communis*). When the worms are full fed and show signs of spinning, they are put into baskets containing dry leaves or shavings. Dry mango leaves have been found successful. After seven to ten days the cocoons are picked out and cleaned, and then placed in a tray.

The author advises the isolation of laying females in order that the egg masses may not become mixed, for it is of great importance that the silk rearer be assured that various egg masses are free from the pebrine disease which is transmitted to the egg.

After the moth has emerged the cocoon contains the chrysalis and cast off skin of the worm. An ingenious little machine was invested by CORYTON for LEFROY which turned the cocoons inside out rapidly and efficiently, and the debris thus was readily removed.

The following figures may be used as a guide to the producer: — 1 oz. of seed (eggs) should give approximately 112 lb. of green cocoons, which would dry down to about 36 lb. of clean dry cocoons — the products accepted by the silk spinners.

The following table gives the details approximately for 1 oz. of eggs (30.000 to 35.000 eggs) with regard to the quantity of food, and the space required: —

Stage	Days	Food in lb	Area in sq. ft.
1	5	4	1
2	4	12	9
3	6	40	30
4	7	112	100
5	10	700	200

FARM ENGINEERING.

190 - **The "Excelsior" Motor Plough.** — DESSAISAIX, R., in the *Journal d'Agriculture pratique*, Year 84, No. 52, pp. 514-515 + 1 fig. Paris, Dec., 23, 1920.

The "Excelsior" motor plough, made in Czecho-slovakia, and sold in France by M. A. RAVAUD (1, rue des Italiens, Paris) took part in the demonstrations held recently at Chartres (France). The 4 cylinder engine, developing 35-40 H. P., is mounted in front of the driving wheels, which are provided with short land grips, placed at right angles to the spokes; one of these wheels travels in the furrow. The driver is protected by a hood and the steering is controlled through the steering wheel placed behind the chassis.

---

(1) See *R.* Sept., 1912, No 1331.

The lift is automatic when the reverse is put in. The width of the plough is about 4 feet.

The makers claim that the Excelsior will plough 7.5-12.33 acres in 10 hours at a depth of from 4-15 inches, consuming between 2.5-3 gallons of petrol per acre. At Chartres the Excelsior ploughed 4 174.56 sq. yds. in one hour. In the appended illustration the plough bodies are raised in order to show the position of the stays. A frame in sections, which bolts on to the projecting flanges of the grips is provided for road transport.

Excelsior motor plough

In the illustration the off-side driving wheel is completely fitted with this frame, the frame having been only partially fitted on the near wheel.

The Excelsior motor plough can also be used for hauling various implements and it is provided with a pulley mounted in front for belt-driven machinery.

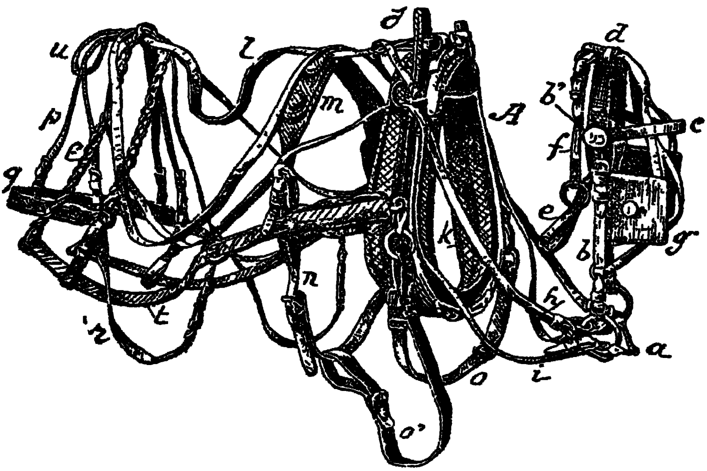
191 - **Horse Harness.** — RINGELMANN, M., in the *Journal d'Agriculture pratique*, Year 8, No. 53, pp. 533-534 + 2 figs. Paris Dec., 30, 1920.

Several articles were published in 1919 by the *Journal d'Agriculture pratique* on harness for farm horses. The type of harness which required examination most was that of the liberated regions of France where reconstruction has to be proceeded with as quickly as possible. This is why studies were made of the harness of the following departments of France: Nord, Pas-de-Calais, and the Aisne (1919, No. 24 and 1919,No 13), Somme

(1919, No. 26) Marne (1919, No. 45), Ardennes (1917, No 13 and 1919, No. 29), Lorraine (1919, Nos 16 and 34) then certain types of interest to the departments of Meurthe-et-Moselle, Meuse, and Vosges (1919, No. 10). In these studies the weight and sizes of all the chief part were given remembering that the dead weight of the harness should be reduced without impairing its strength.

American harness (see figure) is generally lighter than that used in France, Gt. Britain, Brittany, Luxemburg, Holland and most probably in the Rhineland.

The headstall comprises a snaffle bit *a*, cheek straps *b*, and rosette *b'* brow band *c*, crown *d*, throat lash *e*, lash strap *f*, blinkers *g*, reins *h*, and guides *i*. The pull is taken by the collar furnished with wooden hames *j*, and padding *k*. The leather traces *t* are long and end in the chain traces *t'*. They are held by straps from the saddle *m*, and a girth *n*. A shaft strap *o* is fastened to the collar for use with mowers and harvesters. In France, this strap is fastened below the collar and frequently gets in the way of the horse. This is reduced by fixing a support or forecarriage to the shafts of the mowing, reaping and harvesting machines. At *o'* is a spacing strap. The breeching consists of a long crupper *l*, passing from the collar, under the saddle and finishing in a tail-band *u*; hip-straps *p*, support the breeching *q*, which is jointed to the traces, just behind the girth, by breeching straps.

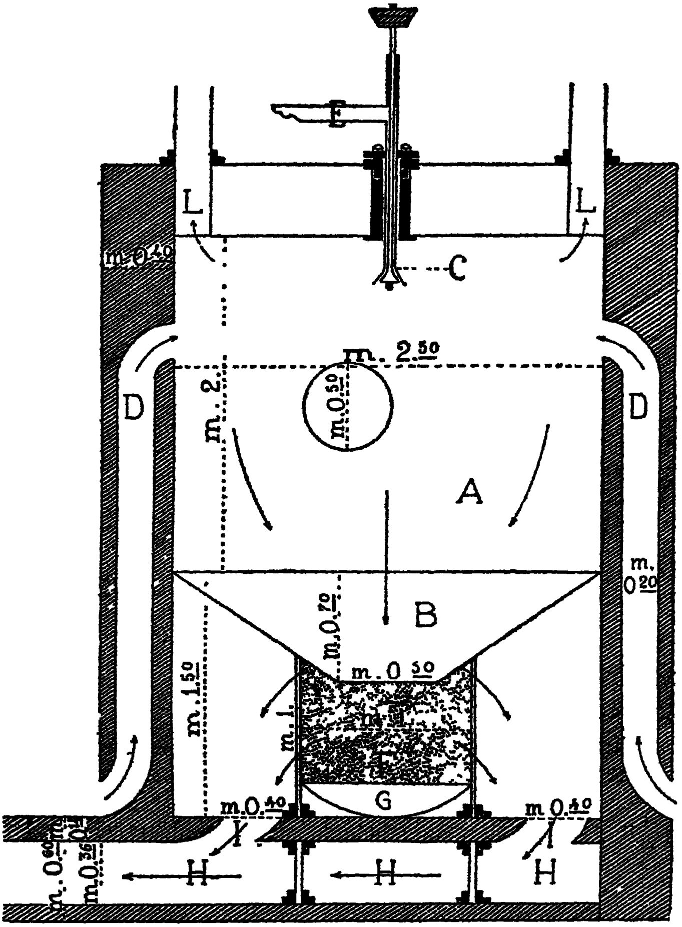


American harness.

This American harness is made of black leather, with a felt collar band and is very well finished

192 - **A Hot-Air Drier for Making Soluble Milk Powder.** — CABIZZA, A M (Buenos Aires), in *L'Agricoltura coloniale*, Year XIV, No 8, pp 321-325 + fig 1 Florence, Aug, 1920

Milk powder, as made in Australia, Madagascar, Liberia, etc., by machines with cylinders superheated with dry steam at 115-120°C is insoluble and, consequently, unable to replace natural milk. On this account it is not much used.



Hot air drier for making soluble milk powder.

The author has invented a hot air drier (CABIZZA, Patent No. 15 665 Argentine Republic) which produces perfectly soluble milk powder retaining its natural colour i. e. , which has not been partially burned.

This drier consists of a chamber *A* built of insulating material such as reinforced concrete lined internally with porcelain, an inverted funnel *B* also lined with porcelain, a sprayer *G* which can be regulated from the outside and has an inlet pipe *E* which communicates with a copper circular tank. The recipient *G* is provided with a hole and discharge pipe *H* with ports at *I*. Four inlet pipes *D* in the walls of *A* admit hot air from a furnace. The milk is previously heated and passes into a compression chamber whence it passes at a pressure of 10-12 atmospheres into the pipe *E* and thence into the sprayer *C* which sends it into the chamber *A* in a fine spray. Here it comes into contact with a continuous stream of hot air from the pipes *D*, by which the solids are separated from the vapour, which escapes through the exhaust ports *L*. The solid matter falls in the form of a fine powder arriving at its maximum dryness just as it passes through the funnel *B* into the recipient *E*. From *F* the milk powder falls into *G* whence it is aspirated into a recipient placed out of contact with the heat whilst the hot air passes out through the fine meshes of the recipient into the exhaust *H*. The circulation of the air through the furnace into the chamber is maintained by one or more pressure fans.

With this method, coagulation of the casein and carbonisation of the sugar which renders the milk insoluble, is avoided. The milk does not come into contact with any metal during this process, and it occupies the greatest possible area as it is in the form of very small globules, so that these are thoroughly dried. As regards yield, 100 litres of fresh milk give 12.5 kg., of dried milk. The cost of a plant capable of treating 10 000 hectolitres a day is 500 000 *pesos* (£ 100 000 at par).

The author considers that this industry should be taken up in countries such as the Argentine, which are rich in cattle and where the cheese industry is of secondary importance and in those countries such as Italy, where there are fewer cattle. but the cheese industry is well developed so that the cheese factories can dispose a much larger amount of milk.

193 – **The Round Barn.** — Fraser, W. J., in *Circular No. 230, University of Illinois, Agricultural Experiment Station*, pp. 3-52, figs 52. Urbana, Illinois. September 1918.

The author states that the round barn may be adapted to the requirements of various types of farming and that the farmers who had already used them were unanimous in declaring them economical in construction and convenient for the feeding and care of stock. The circular construction takes advantage of the lineal strength of the lumber, which is some twenty times that of the cross-grain shearing strength, thus making it possible to use smaller or fewer pieces than are ordinarily used in a rectangular structure. The studs in a round barn may be placed 2 feet to 2 feet 6 inches apart, in comparison with the 16 inches spacing in the rectangular form; yet the circular wall is stronger. Another item of economy is in the requirement of less framing lumber as not a single framing timber larger than 2 × 8 feet is needed above the joist. If the siding is put on vertically and a hip roof is built, no scaffolding is required inside or out during construction

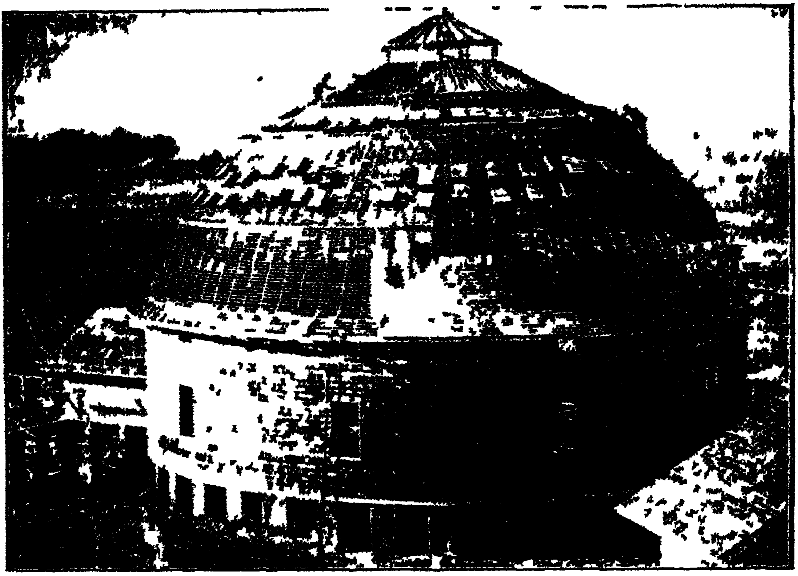


Fig 1 Circular barn during construction

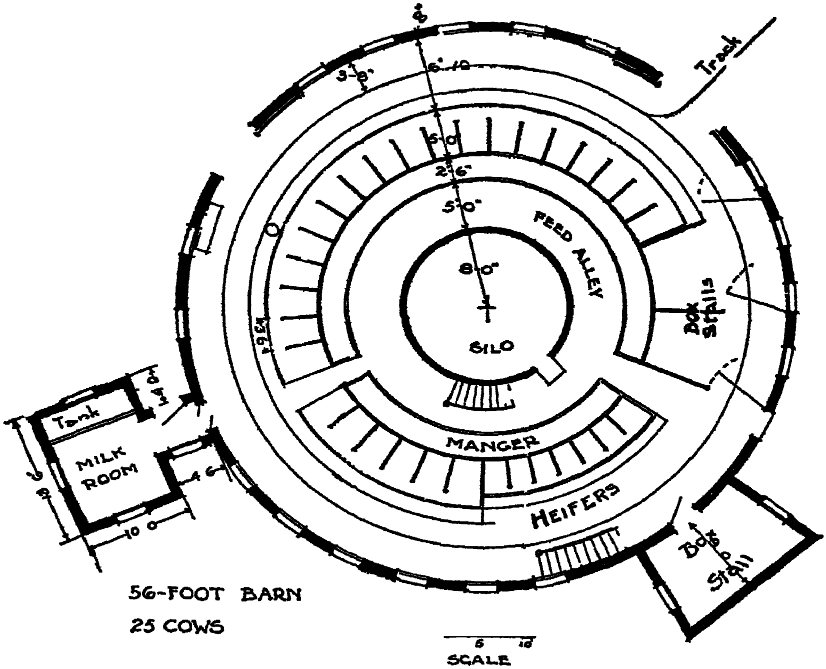

Fig 2 Plan of a circular barn for 25 cows

The objections raised with regard to the difficulties of lighting, and that rectangular objects cannot be placed in a circle without waste of space can easily be overcome, by properly spacing the windows well up towards the ceiling and by building circular silos etc,, and especially designed hay tracks A high board fence radiating from the barn acts as a wind break.

A comparison between the amount and cost of material in round and rectangular barns has been made by an expert barn builder. Round barns 600 feet and 90 feet in diameter, constructed entirely of wood are compared with both plank and mortise frame rectangular barns containing the same number of square feet of floor space.

Round and rectangular barns of the same area and with 20 ft posts not including foundation and silos.

Materials	Round barn 60 ft in diameter Per 1000 ft.	Rectangular barn 31 × 78 ½ feet Plank frame	 Mortise frame
Framing lumber.	13 976 ft. at $ 33 =$ 461.20	19 833 ft. at $ 33=$ 654 49	29 074 ft. at $ 33=$ 959 44
Sheathing siding and flooring	12 971 ft. at $ 35=$ 453 98	15 355 ft. at $ 35 = 537.43	15 355 ft. at $ 35=$ 537.4
Shingles	14 000 ft. at $ 4 50=198 00	45 000 ft. at $ 4.50 = 202 50	45 000 ft. at 4.50 = 202.50
Bolts	—	20 88	—
Total cost of lumber . .	$ 1 113.18	$ 1 415 30	$ 1 699 47
Proportional cost . . .	100 %	127 %	153 %
Content, cubic feet . .	117,669	117,128	117,138

The rectangular barn has stall room for two more cows than the 60 feet round barn but this is compensated for by the fact that the latter contains space in the centre for a silo 18 feet in diameter.

A 90 foot round barn with 20 foot posts has a capacity of 33 000 cub. feet in excess of the rectangular barn measuring 32 × 36 feet with 20 foot posts and with a stable below.

Full details with illustrations are given showing the roof cupola, and door constructions and the hay outfits. The diagram shows a round barn that is giving satisfaction.

RURAL ECONOMICS

194 - **Agricultural Accounting in Norway during 1918 and 1919.** — *Tidsskrift for det Norske Landbruk*, Year XXVII, Part 8, pp. 312-319 Christiania, Aug, 1920.

For the agricultural year 1918-1919, there were 28 accounts sent in by Ostlandet, 18 by Tröndelagen 24 by Vestlandet, 21 by Sörlandet, 7 by Nordre österdalen, 4 by Nordland or 102 in all. The period covered is from April 1, 1918 to March 31, 1919.

The prices of the chief agricultural products have risen in comparison with 1917-1918, but not to such an extent as in 1916-1917 and 1917-1918. In certain cases the price of cereals showed a tendency to fall.

TABLE I. — *Average percentage yield of the chief crops.*

	Hay		Seeds of forage grasses	Cereals				Potatoes	Turnips
	Artificial meadow	Natural meadow		Oats	Barley	Rye	Wheat

1) Land capital	294 46	281 11	411 31	480 47	391 15	244 25
2) Gross receipts	139.17	146 30	141 39	195 17	120 84	118 71
3) Expenses . .	73 51	70 20	106 60	132 03	84 85	52 59
4) Net receipts.	63 66	76 10	34 79	63 14	35 99	66.12
5) Interest on circulating capital	22.67	27 4	8 67	13 01	9 85	24.83

(1) According to a publication by the Norwegian Agricultural Statistics office, th unit of area (not specified here) appears to be the *Maal A erland* of 0 9844 hectare 1 gol Krona = 1.389 fr. at par (*Fd*)

This table shows that the circulating capital has increased since th preceding year, owing to the continual rise in prices.

The Superintendents' salaries in Kronor per day, those for 1917-191 being given in brackets, were as follows — Ostlandet 12 11 (18 76) Tröndelagen 9 67 (7 38) ; Vestlandet 9 78 (6 57) , Sörlandet 10 38 (7.29) Nordre Osterdalen 9 77 (6 57) ; Nordland 9 55 (6 75)

Labourers' salaries per day averaged 9 28 kr in summer and 8 26 kr in winter.

The net receipts have greatly increased in Nordland and Tröndlage not so much in Ostlandet, and are roughly the same as the preceding yea in Vestlandet In Sorlandet they have decreased by 10 % and in Nordr Österdalen by 20 %.

TABLE III. — *Cost of cultivation and gross receipts in Krona per unit area*

	Östlandet	Tröndelagen	Vestlandet	Sörlandet	Nordre Österdalen	Nordland
Expenses:						
Fertiliser	5.39	4.23	2.61	7.08	1.76	1.97
Concentrated goods	11.75	6.53	4.68	19.11	6 31	4.25
Manual labour	43.14	48.71	85.60	84.47	64.01	38.96
Other expenses	15.83	10.73	13.71	21.37	12.77	7.41
Total	**75.51**	**70.20**	**106.60**	**132.03**	**84.85**	**52,59**
Gross receipts:						
Crops	64.90	59.96	27.10	57.08	7.39	30 63
Cattle	69.30	81.07	102.45	171.51	108.18	84.69
Land and house rents	3.86	4.29	7.36	4.54	4.93	2.85
Other receipts	1.11	0.98	4.48	2.04	0.24	0.54
Total	**139.17**	**146.30**	**141.39**	**195.17**	**120.84**	**118.71**

These tables show that the results were, on an average, very good in all the provinces, and that it can be said that those farmers who sent in their books are possessed of intelligence and energy superior to the average in their respective provinces.

195 – **The Cost Price of Wheat in the Region of Toulouse and the Pyrenees, France.** — COUZINET, in *La Vie Agricole et rurale*, Year IX, Vol. XVII, No. 41, pp. 231. Paris, Oct., 9, 1920.

The following statistics give the average production of wheat per hectare in Toulouse and the Pyrenees.

	Francs
12 hl. per hectare at 88 fr. per hl	1 056
Value of straw 15 fr. per 100 kg.	180
Total per hectare	**1 236**

	Francs	
Labour: 3 preparations at 150 fr p. prep. per h. or per 12 hl, i. e. 450 fr. for 12 hl. per 1 hectolitre	37.50	
Fertilisers: 400 kg. superphosphate per h., 120 fr. for 12 hl. per 1 hl.	10.00	
Seed: 2.40 hl. per h. at 90 fr. per hl. 216 fr. per h. per 12 hl., per hl.	18 00	
Two harrowings and 1 weeding: first to cover seeds, second, in spring, to break down surface at 60 fr. per hectare, per 1 hl.	5.00	
Cost of harvesting: Stacking, transport, threshing, preparation. — *Note*: Because of laid straw in some parts, manual labour is necessary	10.00	
Carried forward	80.50	**1 236**

	Francs	Francs
Carried forward . . .	80.50	1 236
Cost of threshing: Contractor per hl.	3.00	
Coal, 450 kg. per 100 hl.: 50 fr. per 100 kg. storage: i. e. 225 fr. i. e. per hl.	2.25	
Food for 3 contractor's men: 45 fr. per day or per 100 hl: 8 i. e. per 1 hl.	0.45	
Staff. 20 persons at 15 fr. per day (food included), i. e. 300 fr. per 100 hl	3.00	
Loss due to bad weather, breakages to machine, moving, and contingencies	1.30	
Total cost price per hl. . .	90.50	
Therefore per hectare 90.50 × 12 = ...		1 086
Difference or profit		150

This profit will pay the " fermage " or interest on land capital, ensure the upkeep and amortisation of material, etc.

196 – **Cost of Pork Production.** — See No. 184 of this *Review*.

AGRICULTURAL INDUSTRIES

197 – **Apiculated Yeasts in the Fermentation of Wine.** — De Rossi, G., in *Le Stazioni sperimentali agrarie italiane*, Vol. LIII, Parts 7-8-9, pp. 233-297 + 8 diags., bibliography of 134 works. Modena, 1920.

Apiculate yeasts are widely distributed in nature. They not only take part in the process of vinification of fruit juices, but also in a number of other spontaneous processes of alcoholic fermentation. Different authors have given these yeasts a considerable diversity of characters. It is due to this that the conviction has been held for a long time that they comprise a certain number of distinct races of varieties as regards appearance, size. fermentative activity etc. Recently it has been demonstrated that the collective species *Saccharomyces apiculatus* can be divided into several distinct species. Some of these, capable of producing spores, belong, according to Zikes, to a new genus, *Hanseniaspora*, whilst the asporigenous forms for which the name *Saccharomvces* appear unsuitable, has been named by Klöcker as *Pseudosaccharomyces*. Klöcker has described 16 species of *Pseudosaccharomvces*, but the differences between their characters are not very clear and it is certain that more careful examination would reduce their number considerably. Will has described 3 species which he named *Pseudosacch. vini* and *Pseudosacch. cervisiae*.

The author has found, on the grapes and in the must of the Umbrian region, 2 apiculate forms, which a microscopical examination of recently prepared cultures, has served to differentiate clearly and which show different physiological aptitudes. One form showed characters that closely resembled those common to apiculture ferments, and the author proposes to call it *Pseudosacch. apiculatus*. The other, which is more rarely isolated, the author names *Pseudosacch. magnus.* The author has not thought it opportune to try to subdivide these 2 species still further according to the differences which can be observed in the various strains which were examined; these differences, generally of a quantitative nature, were very slight, and did not group together sufficiently to constitute the characters proper to one or more parent strains *Pseudosacch. apiculatus* is a low yeast, whose cells, in liquid or solid cultures of recent date appeared chiefly apiculate. Only a few are oval or assume another form. They are isolated or united two by two; they usually measure 3.4 to 6 × 1.5 to 3.2μ but some are much larger. They stain with Gram's stain, and they sometimes show the reaction of glycogene. They often contain metachromatic granules and corpuscles which give the microchemical reaction of fats. Spore formation has never been observed. Grape must, a decoction of glucose yeast, as well as gelatine and agar prepared with these liquids, makes excellent cultures for growing *Pseudosacch. apiculatus.* It will grow equally well on other nutritive media, provided that they contain glucose. The minimum temperature for growth varies between 1° and 3.5°*C.*, the maximum between 31° and 33.5°*C*; the lethal temperature applied for 10 minutes to cells suspended in grape must is 44°-47°*C.* All the strains of this species will ferment glucose and alvulose, but not maltose or lactose, nor saccharose, except about twice out of 39 times. The quantity of alcohol produced in 20 days, at 15°-18°*C.*, from grape must was 3.15-4.55 % by weight. This species also considerably reduces the fixed acidity of grape must and it produces a rather large quantity of volatile acids. It sometimes resists 0.3 per 1000 of metabisulphite of potassium, sometimes none at all, it is thus much more sensitive than the ellipsoid ferment to the action of this antiseptic.

Pseudosacch. magnus is also a low yeast which in recent cultures shows large apicula cells, generally of uniform appearance and size, they measure 4.8 to 9 × 2.7 to 4.8 μ and are isolated or coupled, or even especially during the firsts tages of development, arranged in groups of 3 or 4, without lateral ramifications. When the culture is growing old very varied, forms of cells appear. Numerous other characters of this species resemble those of *P. apiculatus,* with the following exceptions: – 1) The gelatin is liquified; 2) the temperature of maximum growth is 33°-35°*C*; 3) The lethal temperature for 10 minutes in grape must, is 49°-50°*C*; 4) the amount of alcohol produced in 20 days at 15°-18*C* from grape must is 8.30-9.15 % (by weight); 5) the quantity of metabisulphite of potassium resisted is 0.7 per 1000. This species cannot be identified with any of those previously described. The author's researches have shown that *P. apiculatus* has a much smaller activity and fermentative power than *S. ellipsoideus* whilst *P. magnus* in the first place has a weaker fermentative but a slightly superior fermentative capacity than the races of *Sacch ellipsoideus* experimented on by the author. The two apiculate species are equivalent as far as they cause, compared with the ellipsoid ferment, a greater decrease in the fixed acidity of grape must and a greater production of volatile acidity.

The well-known fact that *P. apiculatus* grows much more rapidly than *Sacch. ellipsoideus* has also been confirmed; for this reason the apiculate yeast dominates in the first place in grape must which contains the two blastomycetes. But as it is very sensitive to the action of alcohol, it soon suspends growth and after some days it decreases in number whilst the ellipsoid type continues to increase, so that by the end of the fermentation it greatly predominates and often appears to have completely replaced the apiculate forms. As for *P. magnus*, the author states that its vegetative activity is nearly equal to that of *Sacch. ellipsoideus*, but it is the first to become exhausted in the symbiosis of the two yeasts, so that by the end of the fermentation the ellipsoid species dominates.

The numerous experiments made by the author under different environmental conditions and with various media prove that *P. apiculatus* and *P. magnus* do not at all alter the result of fermentation, when they develop in the must at the same time as *Sacch ellipsoideus*. The speed of fermentation is slightly less because of *P. apiculatus*, but in this case the final result, *i. e.* the alcohol content of the wine, does not differ from that produced by *S ellipsoideus* alone. Liquids which have undergone mixed fermentation have generally less fixed acidity than those fermented with the ellipsoid yeast only; and the volatile acidity also is not increased more than by the mixed ferments, but is sometimes a little less. The author does not agree with the current opinion, based on the experiments of MÜLLER-THORGAU and others, that apiculate ferments, competing with ellipsoid yeast, have an unfavourable influence on wine-making from grape must by rendering the fermentation incomplete; it does not appear that they produce a disagreable taste and smell.

Several experiments on wine-making confirm the fact that the activity of *P. magnus* is not harmful. When the pure culture of this blastomycete was added to a must, the spontaneous fermentation of which had been stopped by sulphuration, the benefit of a slightly increased yield of superior tasting alcohol was obtained, not only in comparison with that obtained from the spontaneous fermentation of non sulphurated must but also with that of sulphurated must inoculated with a pure culture ot *Sacch. ellipsoideus*.

198 - **Causes of the Disappearance of Coal-Tar Dyes in Wine** (1). — MAZZARON, A , in *Le Stazioni sperimentali agrarie italiane*, Vol LIII, Parts 4-5-6, pp. 172-183, bibliography of 9 publications. Modena, 1920.

The author has previously shown that coal-tar colours added to wine in time undergo changes which can not be discovered with the usual analytical methods; hence the importance of all research on this subject, not only because of its bearing on the laws regulating the sale of wine but also to establish the causes and conditions which are most favourable for this process, and by what agency the colour is made to disappear.

The author summarises the researches of FALLIÈRES, MARTY, CAZE-

---

(1) See *R.* May 1920, No. 580. (*Ed*)

NEUVE, MONARON, and others, and then describes his own work, and draws the following conclusions: —

Light is the principal, perhaps the only, agent of the phenomenon, but its action is subordinated to the presence in the wine of natural or unnatural substances, such as lactic acid, malic acid, citric acid, sulphur dioxide, sulphites, etc.

The chemical action leading to the transformation of the dye may be as much due to oxidation as to reduction.

All, or nearly all, the commercial dyes sold for this purpose undergo the same process. Oenotamic and other substances natural to the wine will not always form precipitates when artificial colouring is added to the wine, since oenocyanine and oenotannic acid added to distilled water containing a dye do not give a precipitate, and since, in some sterilised wine, the dye disappears, a precipitate being formed.

Neither is the alteration of the composition of the wine due to micro-organisms a direct or sole cause of the disappearance. But they may help by producing substances which facilitate the action of the light.

It does not follow that, as FERRAND believes, the dye added to the wine may cause the alteration and subsequent transformation

The author concludes by remarking that in all law-cases of fraud in connection with wines, the wine, before examination should be kept in coloured, non-transparent bottles and as much as possible shaded from the light.

199 - **The Disadvantage of Using Yellow Paraffin Oil in Wine Making.** — GRIMALDI, S., in *L'Italia vinicola ed agraria*, Year X, No. 50, pp. 597-598. Casalmonferrato, Dec. 12 1920.

The oil colour for wine making recently put on the market is stated by the author to consist of paraffin coloured yellow by tropeoline, and he draws attention to the fact that this coal-tar colour passes with the oil into the bottled wine, thus producing illegally an artificial colouration of a wine that is otherwise unadulterated.

On account of this the Italian Ministry of Agriculture ordered by circular, No 24,609 of Sept. 8, 1917, that paraffin oil coloured yellow by tropeoline, called also " enolio " should not be used in wine making.

200 - **Levulose Syrup and its Possibilities with Artichokes.** — WILLAMAN, J. J. (University of Minnesota), in *Science*, Vol. LII, No. 1346, pp. 351-352. Lancaster, Pa., October, 15, 1920.

The possible yield of sugar from the Jerusalem artichoke compares very favourably with that of other sugar crops, and the author considers that levulose syrup from artichoke tubers is one of the most promising of sugar possibilities. This in the form of inulin is found to the extent of 12 to 14 % in the fresh tuber. Assuming 40 000 lb. per acre and a 10 % recovery of inulin, there would thus be 4 000 lb. of sugar per acre. Compared with this; an acre of good sorghum yields about 1 600 lb. of sugar; an acre of sugar beet 3 000 lb; an acre of sugar cane 3 000 to 4 500 lb. These figures are estimates based on known yields and analyses of artichokes. Although the direct method of isolation of the inulin and its hydrolysis to levulose on a commercial scale is uncertain, the knowledge of the chemistry of these substances makes it very probable that the problem connected with the manufacture of levulose syrup could be solved. The question of the cost of production is at present unknown, but as the resultant product would be decidedly sweeter than any of the present sugars, it would be worth considerably more, in spite of the fact that the actual cost of manufacture might be higher

In view of the obvious advantages connected with this product, the author advises the inauguration of investigations in order to still further augment the present sources of sweetness.

201 - **Nomenclature of Flours, Starches, and Fecula.** — I LINDET, in the *Comptes rendus de l'Académie d'Agriculture*, Vol. VI, No. 38, pp. 903-904 Paris, Dec. 15, 1920. — II. JUMELLE, H, *Ibid.*, Vol VII, No 2, pp. 50-51. Jan. 12, 1921.

I. — The "Chambre syndicale des fabricants de glucose de France," considering that the names "flour," "starch" and "fecula" were badly understood both in Customs tariffs and in commerce generally, asked M ARPIN, an expert on these matters to report on this sybject.

M. LINDET communicated the main points of this report to the Academy:

It is not difficult to define the name "flour":— Flours are the produce obtained by milling plants containing starch as well as nitrogen and salts. But this does not hold for starch and fecula. Usually the name starch is given to the amylaceous substances which are found in the aerial organs of plants, such as maize starch, wheat starch, rice starch. Fecula is defined as the amylaceous substances contained in those parts of a plant which grow under the ground, such as the fecula of potatoes, etc.

But to this loose definition, M. ARPIN adds another and says that starch from seeds has the singular property of forming small columns called needles or crystals, when dried under certain conditions, whilst fecula always remains as powder, no matter how dried.

M. ARPIN suggests that this method should be used for defining amylaceous substances instead of by their origin in aerial or sub-terranean parts of the plant.

II. — M. JUMELLE states that the term starch is generally used for amylaceous substances extracted from grain, and fecula for that extracted from any other part of the plant.

For example the name fecula is given to very different amylaceous substances such as banana flour, feculant fruit such as bread-fruit, chayotte, etc., the trunks of palm-trees and of Cycadaceae (sagos), etc.

202 - **Variations in the Composition of wheat.** — LINDET, ROUSSEAU, E, and SIROT, in the *Comptes rendus de l'Académie d'Agriculture de France*, Vol. VI, No. 31, pp. 753, 754, 758-762. Paris, Oct 27, 1920.

A note by MM. ROUSSEAU and SIROT communicated to the Academy by M. LINDET.

The authors have previously remarked that the quantity of soluble nitrogenous substances contained in good flour is very nearly constant, and that by this means the bread-making qualities of flour can be judged. Since then the authors have analysed wheat grain in all stages of development, including grain soaked by rain, to the time of germination. The proportion of the soluble to the total nitrogenous matter, which was 49 % at the end of June, fell to 10-14 % by the end of July, and increased to 36 % under the influence of germination.

The authors also studied the parallel progress of the soluble and total phosphates. The proportion of soluble to total phosphates was 76 % at the beginning of grain formation, fell to 35 %, and then reached 42 %.

The acidity follows the same curve; it started at 0.300, fell to 0.030 and rose again to 0.050. It can therefore be said, in agreement with previous research, that an abnormal composition of the wheat corresponds to insufficient maturation or a tendency to germination.

203 - **Action of Hydrogen Peroxide on Flours.** — MARION, in the *Comptes rendus de l'Académie des Sciences*, Vol. CLXXI, No. 17, pp. 804-806. Paris, Oct., 26, 1920.

All flours contain a catalase in a quantity which varies with the degree of bolting; the by products from milling contain the maximum amount.

By measuring the volume of oxygen liberated in a given time from a given quantity of hydrogen peroxide a given weight of flour being used, an indication of the degree of bolting of the flour can be obtained. This method is more accurate and rapid than the various chemical methods employed.

204 - **Baking Value of Wheat.** — SANDERSON, T., in *Bulletin No.* 137, *Agricultural Experiment Station, Agricultural College, North Dakota*, pp. 1-45. North Dakota, May, 1920.

The data included in this Bulletin show the results of investigations for several years; for this reason only a summarised report for each one hundred experiments is given which shows:

1) The standard for the wheat flour;

2) The variation in quality and value of each sample, with the average result of milling and bread making classified in first and second grades relative to the yields 1916-1919.

The author maintains the opinion that if an adequate system of grading and determination of the milling and baking value is adopted, these experiments could be applied practically and would prove of considerable economic value.

205 - **Castor-Oil Industry.** — SHRADER, J. H., in the *United States Department of Agriculture Bulletin*, No. 867, pp. 1-40, Figs. 15. Washington, D. C., Sept. 3, 1920.

While castor oil from *Ricinus communis* is more widely known for its medicinal properties, its use is being constantly extended in a variety of industries. The hydroxylated condition of this oil is probably the property which renders it so valuable, for it is apparent that when other oils are treated so as to increase their acetyl number and their viscosity, they are more inclined to act in a way similar to castor oil e. g. the hydroxylation of acids normally soluble in gasoline, renders them insoluble, The industrial uses are enumerated as follows: — The manufacture of 1) artificial leather to impart softness and elasticity to the otherwise stiff product; 2) leather, to give flexibility to belting and for lubricating purposes; 3) emulsifying and cutting oils in connection with water; 4) Turkey red dye; 5) mantle dips; 6) linoleum; 7) rubber substitute (after treatment with sulphur and vulcanisation); 8) tire cement; 9) varnish; 10) textiles (castor soap oil); 11) copying inks, etc. For ordinary lubrication of machinery, the viscosity of this oil is its great asset and it is largely used by engineers.

In addition to details with regard to these uses, the author describes the analysis of a commercial sample of castor beans showing that the whole bean consists of 35 % seed coat and 65 % kernel, the oil content of these two parts being 10 and 62.9 % respectively. Contrary to the common belief that the colouring matter extracted by the solvent process is introduced through the so-called germs, it has been proved that the colour seems to be chiefly derived from the seed coats and is evidently not a single simple substance.

At least a small amount of acid was found invariably present in the beans. An acid determination of selected beans would create a standard towards which to work, although the percentage could not be realised in actual commercial practice.

The author touches also in detail on the following points: 1) trade and commerce; 2) the inspection and valuation of castor beans and 3) the manufacturing processes connected with castor oil.

I. — The normal annual consumption of castor oil in the United States is more than 2 000 000 gallons, and almost all is produced by her own crushing plants. The average annual importation of beans for the 5 fiscal years ending June 30, 1917 was about 834 00 bushels, and that of oil was comparatively insignificant.

The following Table shows the relative quantities imported from various sources during the years 1912, 1914, 1918.

Source	Relative importations of castor beans %		
	1912	1914	1918
United Kingdom	14.0	10.0	0.06
India	81.0	87.9	60.00
South America	4.6	1.0	19.00
West Indies	0.1	0.3	8.00

The author states that the great campaign of castor bean growing inaugurated in 1917 by the *Bureau of Aircraft Production* has led to the possibilities of creating a permanent American industry in this respect.

II. — To avoid judging the oil in the beans approximately only, it is suggested that the more logical proceeding would be judge them on the quantity and quality of the oil actually contained in the beans in addition. to the test for impurities. Methods at present employed are described in detail.

III. — After the cleaning process, the beans undergo decortication Owing to the peculiar structure of the castor bean, special machines have been built for this purpose to shake the kernels out of the adhering seed coats and otherwise to break up the mass. The next proceeding, namely heating, is to a large extent conducted on the " small assembled heater " system. The actual heating is effected by rising columns of hot air. The discharge may be made continuous or intermittent. Illustrations are given showing the construction of the above mentioned heater for this purpose.

As it is generally conceded that better oils are obtained when appreciable quantities of moisture are present it is advised that a jet of live steam should play into the descending current of material just before it enters the expeller. This gives a dry interior to the oleaginous material and a wet surface The drying effect on the beans would improve and greatly simplify decortication by rendering the seed coats more easily separable from the kernels.

In the past, plate presses and cloths were used for crushing the beans. This method has been abandoned for that of the " cage press. "

The other method used in modern oilseed milling which has been applied to castor bean pressing is that of expelling the oil in Anderson oil expellers. Unless proper care and skill are applied these machines produce an oil high in meal. Moisture and heating are therefore essential preliminaries. This process produces an oil of satisfactory quality for all industrial uses, and is especially suitable for aeroplane lubrication.

On account of the large proportion of residual oil left in the cake from the pressing or expelling operation (from 12 to 20 % or about 5 lb. to 46 lb. per bus), solvent extraction of the cake is universally practiced in America following the method generally applicable to oleaginous products. The units comprising a complete extraction plant consists of the extractor, the solvent recovery still, the oil-finishing still, the condenser, the solvent and water separator, pumps and s orage tanks. Two general types of equipment are used, namely, the stationary and the rotary extractors.

In the course of experimental work on the technology of castor-oil manufacture, evidence has been obtained which indicates that a satisfactory grade of oil, colourless and low in acidity, can be made entirely by the solvent process. As every expelling plant must have an auxiliary extraction equipment, this will mean a material decrease in the cost of production.

The only constituent of real commercial value obtained from the pomace is the ammonia and this is only the case when the moisture runs above 12 % and decomposition sets it.

A survey is given of the various refining and bleaching methods employed. The centrifugal separator is illustrated and is the machine by which meal and other substances are removed, and this leaves an oil with only a thin cloud but which can be treated with fuller's earth, bleached and filtered with much greater ease than with the bulky precipitate retained. Highly acid dark oil can be refined by alkali but not highly bleached while low acid oils can be refined and bleached to almost water white.

The quality of the oil is determined in trade by its colour, clearness and acidity. The specifications made by the Bureau of Aircraft Production giving the properties which a good grade of lubricating oil should possess. are as follows:

1) The oil may be either cold-pressed or hot-pressed and refined;

2) It must be free from adulteration, other oils, suspended matter, grit and water.

3) It must meet the following requirements.

4) When observed in a 4-oz sample bottle, the castor oil must be colorless or nearly so, transparent and without fluorescence.

5) Specific gravity = 0.959 to 0 968 at 60° *F* (Baumé gravity from 16.05 to 14.70 at 60° *F*).

6) Viscosity (tested in a Saybolt universal viscosimeter) not less than 450 seconds at 130° *F* and 95 seconds at 122° *F*.

7) Flash point not less than 450° in a Cleveland open cup-flash tester.

8) In a 4-oz sample bottle one quarter full, the oil must not congeal on being subjected to a temperature of 5° *F* for one hour.

9) The castor oil must not show a greater loss than 0.5 per cent when heated in an oven at 230° *F* for $1^3/_4$ hours.

10) It should not show more than 0.015 per cent of ash nor any impurity of any sort not related to the original product.

11) It must be completely soluble in 4 volumes of 90 per cent alcohol, specific gravity 0.834 at 60° *F*).

12) The acid number must be equivalent to no more than 1.5 per cent of oleic acid.

13) The unsaponifiable matter must not exceed 1 per cent.

14) The iodine number must be between 80 and 90.

15) and 16) The castor oil must not give a reaction either for rosin or rosin oil, or for cottonseed oil.

206 - **Research on Lemon-Oil.** — Bertolo, P., in the *Bollettino delle Sedute della Accademia Gioenia di Scienze Naturali in Catania*, Series II, Part 47, pp.28-31, Catania, 1920.

During the last period of the war, when the supply of fat was becoming very limited, the attention of the author was drawn to the lemon pips left as refuse in the " pastazzo " (marc) from the preparation of citrus products (" agrocotto ") such as calcium citrate, and citric acid. As yet this residue has no commercial value, being only used as manure and, in small quantities, as cattle food. The author therefore examined the oil derived from the pips to establish its nature, concentration, degree of saponification and other constants, and to ascertain its utility as a source of fat. These experiments were so successful that he advises the industrial extraction of lemon pip oil.

The extraction of the oil was made either by pressure or by the aid of solvents (carbon bisulphide, ligroin and benzene). The percentage of oil extracted by solvents varied from 30-35 %, according to the maturity of the pips. The oil obtained by expression is slightly fluid, with a clear yellow colour, an agreeable smell of lemon and slightly bitter taste. The oil apparently is a semi-drying oil and most nearly ressemble cotton seed oil in its characteristics, except that is does not give the HALPHEN reaction.

207 - **Cold Packed Canned Peas, Studies in the Heat Resistant Organisms.** — NORMINGTON, R., GILTNER W. and WYANT, Z N., in the *Technical Bulletin, Michigan Agricultural College*, pp. 5-33, Bibliogr. of 32 works. East Lansing, Michigan, November 1919.

The investigation was carried out with a view to determining the cause, of the very much larger proportion of spoilage among home canned foods compared with those canned commercially.

A comparison was made between peas heated in steam, those cooked by the hot water bath method, and those processed in the autoclave at 15 lb. pressure.

The percentage of spoilage was much lower in pint cans of peas autoclaved than in the other cases. This is the usual commercial method. The commercial canners found also that peas canned immediately after shelling had a comparatively low percentage of spoilage.

All the organisms found during these experiments were spore forming bacilli and resembled *Bacillus subtilis*, and other soil organisms. This indicates the importance of careful washing of peas and other vegetables before canning, in order to remove all soil and dust, and thus the greater part of the organisms.

All organisms withstood from 10-15 lb. pressure in the autoclave for 10 to 20 minutes. It is advised by the authors that the time for processing of vegetables should be lengthened so that the centre of the can may be at a high temperature sufficiently long to kill the more resistant organisms.

The steam pressure method is recommended for all cold packed canned vegetables to insure the greatest probability of success.

Details of the morphology, cultural characteristics, physical and biochemical features, and the temperature relations are given for each group of bacilli isolated. Nearly all the organisms reduced starch to sugar, seven caused peptonisation of milk, and one failed to produce indol from peptone. Eight produced gas in sterile peas but not in other media (*B. subtilis. B. ramosus*, *B. ruber*, *B. prodigiosus* and *B. viscosus*), which suggests additional possibilities in differential identification tests.

The results obtained in the chemical analysis of spoiled peas leads the authors to suggest that the determination of creatinine and ammonia, especially the former, may serve to detect bacterial decomposition in this canned food product.

208 - **The White Cherry Industry.** — I. PARIS, G., in *Le Stazioni sperimentali agrarie italiane*, Parts 4-5-6, pp. 187-227, + 1 fig. Bibliography of 12 publications. Modena, 1920. — II. CARRANTE, V., in *La Propaganda agricola*, Series II, Year XII, No. 22, pp. 342-348 + 2 figs. Bari, Nov. 30, 1920.

I. — The cherry tree is extensively cultivated in the province of Avellino. One tree produces about 2-3 quintals of fruit and most of the crop is exported. Formerly, only fresh fruit was exported but now the " cerise travaillée " *i. e.*, bleached with sulphur dioxide is almost exclusively exported. Before the war Germany, and now the United States consumed most of the exports. Avella and Tufino, and other hard and late cherries are preferred for bleaching. Up to now the operation has been done by empirical metods. The author proposes to replace these by methods deduced from his researches in the laboratory of agricultural chemistry of R. Scuola di Oenologia at Avellino.

The fruit is brought from the country in rectangular baskets 0.70 × 0.35 m. wide and 0.40 m. high. The cherries are then put into small crates, formed of strips with spaces of 7-8 mm. between, which are filled nearly to the top. The crates are then piled one on the other round the walls of the sulphuring room, leaving a space of 10 cm. between each pile and between each pile and the wall.

In bleaching, 20 kg. of sulphur is burned per 50 quintals of cherries, which are left in the room for 10 to 14 hours, according to their hardness. After bleaching, the cherries are put in a barrel filled with a solution of sulphur dioxide (about 40-100 mgm of SO_2 per kg.). Then 3 kg. of salt are added to each barrel, which is of 2-hectolitre capacity and holds 135 kg. of cherries. The cherries are sold for making jam, sugared fruits, etc.

During the sulphuring process the cherries do not lose weight, but when in the air they lose 1 % per day if hard and 2 % per day if soft.

The empirical method of preparing the sulphur dioxide and the sulphurous water (which usually is made by placing uncovered barrels full of water in a cellar and burning the sulphur in the chamber) has several disadvantages and sometimes causes alterations in the cherries, which, become pale and soft, with small cracks and spots on the skin which the author has identified as sub-centicular colonies of an ellipsoid alcoholic ferment (*Saccharomyces ellipsoideus*), with a stomate in the centre. The harm done to the cherries depends chiefly on the low concentration of the sulphur water used as the protecting liquid, on the loss of sulphur dioxide and to rough handling during sorting after the sulphuring. Absolute sterilisation of the cherries is obtained when there is not less than 80 gm., of sulphur dioxide per litre of water.

The normal constituents of the fruit with which the sulphur dioxide combines are principly aldehydes. It combines easily with sugars such as arabinose, lactose, mannose, and glucose. The hydrocarbons proper, starch, lactose, hemicellulose, etc., do not fix sulphur dioxide. Malic and tartaric acids will not fix sulphur dioxide, which combines but little with tannin and pectic substances.

Water can extract decreasing quantities of sulphurous acid from the sulphurated cherries.

This shows that the combinations which form between the colloid substances of the fruit and the sulphur dioxide are not very stable and that, in general, in casks full of cherries and sulphurous water, the quantity of sulphur dioxide contained in the cherries decreases, and the strength of the aqueous solution consequently increases.

The first step towards improving the industry is to utilise more rationally the sulphur dioxide obtained by burning sulphur. As the price of liquid sulphur dioxide is too high, the author advises the use of a tower of the GLOVER type, connected with a small sulphur or pyrites furnace, from the top of which a fine spray of water falls and dissolves the gas.

For work on a smaller scale a wooden tower, about 2 m. high, and with sides 50 cm. wide, containing a series of slightly sloping wooden baffles 40 cm. apart, on to which the water falls, is recommended. This apparatus is also advised for sulphuring grape must (SEMICHON, *Maladies des Vins*).

The cherries which have been stoved contain 500 mgm. of sulphur dioxide per 100 gm. of fruit, but nearly half of this is lost during sorting and grading. Hence these operations and that of putting into barrels should be finished as quickly as possible. Instead of using small crates in the stove, racks about 10-15 cm. broad may be used and so placed that the gas can circulate all round them, both above and below.

The sulphur furnace is placed between the piles of racks about 2 m from them and the earth so that the gas can diffuse evenly; 250 gm of sulphur is enough for each quintal of cherries, 500 gm. of sulphur dioxide being produced. After 6 hours the action is complete. It is best to admit a small volume of air through an inlet tube brought from near the ground outside to near the top of the chamber inside. Technically, it is not correct to admit sulphur dioxide already formed into the stove, as it has to be formed at the expense of the oxygen in the chamber and the results are much better.

This installation can be used for other fresh and also for dried fruits.

The preserved fruit and the grape syrup industries of the province of Avellino represent the best and most suitable means for dealing with large quantities of apples, plums, apricots and cherries, which in normal times fetch a low price only.

II. — DR. CARRANTE comments on the importance of the work of Prof. PARIS and gives some information concerning this industry in the province of Bari.

The importance of the industry in these two provinces is the same, as they both export about 1500 quintals of cherries per annum. In Bari the cherries are brought from the country in panniers. One kg. of sulphur is used per cwt. of cherries and they are left in the stove 5 hours. The barrels hold 2 hl. The amount of protective liquid per cask is 5 litres of water plus 500 gm. of metabisulphite of potash, plus 500 gm. of hydrochloric acid; the water is stirred and 500 gm of metabisulphite and 5 kg of common salt are added. The author advises the industrial establishments in Bari to adopt the improvements which are suggested by Prof. PARIS.

209 – **Use of Blood Serum to Replace Eggs in Making Alimentary Pastes. Some Experiments in Italy** (1). — ARIANA, G (Ufficiale sanitario e medico capo municipale a Reggio Emilia), in the *Industrie Italiane Illustrate* (I. I I), Number specially devoted to agriculture, foods, and food industries, Year IV, sect D, No 7, pp 25 Milan, July, 1920.

During the war experiments were made in Italy on the direct use of blood as human food; at Milan "blood bread" was made. At Reggio

---

(1) For experiments made in France see *R.*, Oct., 1918, No 1168. (*Ed*)

Emilia the "Comitato per la disciplina dei consumi," on the authors' advice, made experiments on the preparation of alimentary pastes using blood serum instead of eggs.

The serum used was prepared at the Reggio Emilia Municipal Slaughterhouse. The blood was drawn direct from the animal (cow) in big copper caul drons, and was left to stand for 24 hours. The serum was then drawn by suction into glass flasks through rubber tubes. The preparation of the paste was not at all difficult. The flour was kneaded with blood serum (to which a small quantity of salt had been added) to bring it to the desired consistency. This was about 1 part by weight of blood to 3 of flour. The flour was then treated in the usual way.

During the first months of the winter of 1917-1918 the committee sold more than 1500 kg. of this paste, which looked and tasted the same as the commercial egg paste, but was not quite as yellow as the home-made article, in which 4 eggs are used per kg. of flour.

If 1 kg. of flour is kneaded with 4 eggs this gives about 20 gm. of protein and 19 gm. of fat and lipoid substances, 1 kg. of flour kneaded with 330 gm. of serum gives 25 gm. of protein and 1.5 gm. of fat and lipoid substances. The food value of this paste therefore is very little less than that made with eggs. The deficiency in fats and lipoids can be made up by seasoning.

The method used to separate the serum naturally and spontaneously from the coagulated blood was very satisfactory. Small quantities were used at a time and the glass receivers were easily washed, having glass tubes and rubber joints. For industrial purposes a much simpler method and apparatus is necessary. The author advises that the blood be defibrinated as soon as it is drawn by beating with rods or balls of glass or some suitable metal, then passing in the centrifuge.

It would be very profitable if a big slaughter house were to erect such an installation. An adult ox furnishes 25-30 litres of blood, giving 15-20 litres of serum. One litre of serum contains nearly 75 gm. of protein (calculated in the dried state), which is equal to that of 15 eggs.

The serum can also be used for other foods, such as confectionery, etc.

210 - **Payment for Milk according to its Fat Content.** — Porcher, C. and Vitoux, E., in the *Comptes rendus de l'Académie d'Agriculture de France*, Vol VI, No. 38, pp. 916-923., Paris, Dec. 15, 1920.

In certain countries milk is bought at a price in proportion to the fat content. The authors maintain that purchase on this basis is insufficient and ought to be supplemented by a factor relating to the quantity of dry fat extract. For this two very simple tests are sufficient, the first being the total fat content determined by the Gerber method and the second, the density of the milk. In addition the "freshness" of the milk, (microbial qualities and cleanliness) must be taken into account. The determination of the acidity of the milk, a usual dairy process, gives an approximate measure of the microbe content of the milk.

211 - **Manufacture of Soluble Milk Powder and the Successful Results to be obtained in the Italian Cheese Industry.** — See No. 192 of this *Review*.

212 - **Neutralisation of Cream. — Rate and Amount of Reaction in Certain Pasteurisers.** — RAMSAY, A. A., in *Science Bulletin* No. 17. *Department of Agriculture, New South Wales*, pp. 3-22 + 2 pp. graphs; Sydney, May 1920.

The laboratory experiments in neutralising the acidity of cream showed that in using sodium bicarbonate, as a neutralising agent, 94 to 104 % of the reduction, which should theoretically be produced, is obtained; and in using lime as a neutralising agent, 88-96 % is obtained.

The factory experiments were made to trace the decrease in acidity at various stages of the neutralisation and pasteurisation of cream for butter manufacture. The "flash" and "batch or holding" system of pasteurisation were employed.

The percentage amount of neutralisation effected in the two systems by using 1) lime and 2) sodium bicarbonate was as follows:—

	Flash			Holding	
	Lime	Sodium Bicarbonate		Lime	Sodium Bicarbonate
	%	%			
5 minutes after addition . .	68	85.9	10 minutes after addition .	65.2	62.5
10 » » »	70 5	96.5	15 » » »	69.9	67.3
15 » » »	72.4	102.7	30 » » »	74 5	77.5
During pasteurisation (additional).	24.1	10.9	60 » » »	86 3	80.1
Final result . . .	96.5	113.6	120 » » »	86.3	85.9

The action of both soda and lime when well mixed with cream was very rapid. The plant in the flash system consisted of two tanks, each of 200 gallons capacity, which were filled from the usual platform tank into which the cream was tipped as received from suppliers, and the usual flash pasteuriser. The method of working was to fill one of the tanks and determine the acidity of the contained cream. By mixing the lime and cream with a wood rake, an equilibrium of the mixture was quickly attained, and more rapidly and uniformly than with the holding system. When the mixture was complete, the contents of the tank were passed through the pasteuriser and collected in a receiving tank. While this was proceeding, the second 200 gall. tank was being filled to the 200 gall. mark, neutralised as above described, and was ready to be pasteurised as soon as the first tank was empty. The process worked smoothly and well.

The following is the chemical analysis of the crumbled lime-powder used: % moisture-nil-insoluble matter 0.28 — Oxides of iron and aluminium, 2.45. — calcium carbonate 4.55. — calcium hydrate, 73.64 — calcium oxide 19.06.

When the mixture was efficient, sodium carbonate was found quicker in its action than lime.

In the case of the holding vats, those containing small quantities of cream appeared to give a satisfactory mixture, but this was liable to become indifferent or even unsatisfactory when the vats were full.

The results, according to the author, open up a field of investigation, as to what becomes of the 14 % of the efficiency of the neutralising agents, when the holding system is employed, and as to the cause of the apparent ultra-theoretical neutralisation caused by sodium carbonate when used with the flash system.

213 - **The Frozen Meat Industry in Brazil** (1). — *Boletim do Ministerio da Agricultura, Industria e Commercio*, Year VIII, pp. 117-118 Rio de Janeiro, 1920.

Brazil has now 10 refrigerating establishments in full working order, 9 of them being under the control of the federal Government, whilst the other is under the Municipality of Rio de Janeiro. In 1918, 444 847 cattle were slaughtered as against 434,842 in 1919; the average price in 1919 being 185 *milreis* per head (One paper *milreis* = 1s 4d at par). The establishments in order of their capacity are: Rio Grande do Sul, S. Paulo, Rio de Janeiro, and the Federal District.

The following table gives details of the meat export:

Total for the year		Total January-August	
	Metric tons		Metric tons
1916	33 601	1916	19 714
1917	66 452	1917	47 281
1918	60 509	1918	45 751
		1919	30 325

214 - **Production and Sale of Wool in Argentina** (2). — In the *Revista de la Asociación rural del Uruguay*, Year XLIX, No. 7, pp. 501-504. Montevideo, July, 1920.

The stock of ordinary wool in the Argentine now reaches about 100 000 metric tons. This enormous accumulation is due to several reasons such as the closing of the factories of Northern France and of Belgium during the war, and an increased demand for fine wool, which gave a higher yield at spinning and could be manipulated more quickly. Today this demand for fine wool still continues, and although the export from Argentina rose from 187 885 bales in the period Oct. 1918-Oct. 1919, to

---

(1) In connection with this subject see Dr. D. DE CAMPOS: A importação de carnes congeladas na Italia, in the *Republica dos Estados Unidos do Brasil, Boletim do Ministerio das Relações Exteriores*, No. 9. pp. 49-58. Rio de Janeiro, 1920. The author gives data concerning the consumption and supply of meat in Italy, predicts a great increase in Brazilian export trade with this market and suggests that financial help and organization will greatly benefit these two countries. (*Ed.*)

(2) See *R.*, July, 1913, No. 837; *R.*, Oct., 1913, No. 1199; *R.*, Jan., 1914, No. 45; *R.*, June, 1914, Nos. 551 and 552; *R.*, Nov. 1914 No., 1063; *R.*, Jan., 1916, No. 112; *R.*, Nov. 1916, No. 1122. (*Ed.*)

227 968 bales in the period Oct. 1919-Oct. 1920, the increase was exclusively in fine wool.

Thus this stock which was not more than 30 000 metric tons at the end of the war, has increased to about 100 000 metric tons distributed in the following centres: — about 25 % on the « Mercado de Frutos » about 8 % warehoused in the capital, and the rest on the farms. It is estimated that 50 000 metric tons is held by the sheep-owners, who are certainly the cause of the present accumulation; in fact, when the price fell from 27 *pesos* (1 *peso* = 20.99 *d.* at par) in 1918 to 18 *pesos* per 10 kg. in 1919, the owners refused to sell and stored the successive clips. As the offers were thus increased and the demand practically ceased, the price fell to 7.50-8 *pesos* per 10 kg.

The rate of Exchange in Great Britain, France, Italy, and Belgium and the increased rate of interest on capital have all had an effect on the lack of market for ordinary wools. Whereas, before the war, money could be borrowed at an interest of 3 or 4 % it is now 6-8 %. The buyers therefore hesitate to lock up money and prefer to buy as they need the material.

On the other hand it is probable that as the British factories will again begin to use ordinary wool and they cannot use the 700 000 bales from New Zealand before December, the Argentine should find a good market for its wool, especially because there is now a big demand for woollen goods and the output of the European factories is very small so that the demand for this wool should gradually increase.

The situation therefore is not without hope but the mistake must not be made of increasing the export of a commodity which abounds in the country and for which there is little external demand. The sales should be spread over a dozen years or so in accordance with the demands from foreign markets.

215 - **Treatment of Unripe Honey. Successful Experiments in Vacuum Boiling.** — WESTBROOKE, G. V. (Apiary Instructor, Auckland), in *The New Zealand Journal of Agriculture*, Vol. XX, No. 4. pp. 246-240. Wellington, April 20, 1920.

By the use of the hydrometer it has been possible to ascertain if honey was ripe before putting it on the market, but the greatest difficulty was to know what to do with honey below the standard gravity.

The author experimented with samples that had slightly fermented, and with a specific gravity of only 1.405. These were boiled for about 10 minutes in a vacuum flask at a temperature of 130°*F*. This boiling at a comparatively low temperature resulted in ridding the honey of its surplus moisture and in eliminating the froth and particles of wax etc. leaving it very clear. After this treatment the honey showed a specific gravity of 1.425.

As a result of this experiment, arrangements were made to treat a large quantity at the Colonial Sugar Refining Company's works and, in conjunction with the New Zealand Honey Producers' Association, about 6 tons of slightly fermented honey was secured from different parts of the Dominion. This honey on being tested, registered from 1.4 to 1.405 s. g.

and analysis showed that the water content was about 20 %. As it was more or less granulated it was found necessary to reliquefy by adding about 25 % hot water, and this enabled it to be pumped into a large vacuum vat. It was then boiled for over half an hour at a temperature of 120°*F*. Tests were made by the author during the boiling process and when a gravity of 1.425 was registered, the heat was shut off and the honey run into tins. It finally registered 1.432 which indicated a very ripe honey.

This honey after being thus treated showed no trace of fermentation, and the strong rank flavour and aroma prevalent prior to treatment, had now disappeared.

It is advised that such honey should be treated before the ferment germs start in it, thus effecting a large saving for the industry.

216 - **Influence of Fermentation on the Starch Content of Experimental Silage** (1). — DOX A. W. and YODER, L., (Iowa Agricultural Experiment Station) in, the *Journal of Agricultural Research*, Vol. XIX, No. 4, pp. 173-179, Bibliogr. of 13 works. Washington, D. C., May 15, 1920.

The work reported was undertaken to determine any changes the starch might undergo together with the nature of these changes and their relation to other important reactions occuring in silage fermentation. The experiments were made with field maize still green, dented and about at its glazing stage. Determinations were made for moisture, total acidity, alcohol, total sugar and starch, and qualitative tests were also made for the transitional products of starch hydrolysis, namely, soluble starch and dextrins.

From the results obtained the author drew the following conclusions : —

Changes in total acidity, alcohol, and sugar are entirely independent of the starch content of the ensiled maize of the silage produced therefrom

The silage solution, the medium in which fermentation takes place, which is in contact with the silage starch granules, reached a N/.04 concentration by the 8th day and almost N/0.5 by the 66th day. Most of this acidity was due to lactic and acetic acids. Strong acids must, according to this, be used and their dilute solutions must be heated. That there was no marked maximum production of alcohol at any time was due probably at first to oxidation of the acetic acid and later to esterification. Unless the rate of fermentation equals the rate of formation of sugar, no formation of sugar from higher carbohydrates, will be indicated after the 8th day.

The first intermediate products resulting from the decomposition of starch were not present in demonstrable quantities. The starch content remained constant throughout the fermentation process, and the granules remained intact, undergoing no physical change that could be detected by microscopic examination . The lack of consistency in the variations and their correlation with the other fermentation changes give further evidence that the starch is not changed.

---

(1) See *R.*, Jan. 1915, No. 77; *R.* Jan. 1916, No. 119; *R.* Feb. 1916, No. 232; *R.* Nov. 1917, No. 1079; *R.* Feb. 1918, No. 121; *R.* Feb. 1919, No. 257; *R.* July-Sept. 1919, No. 1010; *R.* July-Aug. 1920, No. 802; *R.* Oct. 1920, No 1039. (*Ed.*)

Since starch constitutes about 10 % of the maize plant at the time of ensiling, and represents over 400 calories of available energy per kg., the fact that no loss occurs during fermentation is an additional argument according to the authors, in favour of silage as an economical food.

217 - **Investigations in the Ripening and Storage of Bartlett Pears** (1). — MAGNESS, J. R. (Bureau of Plant Industry, United States Department of Agriculture), in the *Journal of Agricultural Research*, Vol XIX, No. 10, pp 473-500, Figs. 8 Bibliography of 17 works. Washington, D. C., Aug,. 16. 1920.

The investigations were undertaken in order to notify: 1) The changes that take place in the pear from various parts of the Pacific coast during the time of development; 2) the effect of the time of removing the fruit from the tree on its content of acid, sugar, starch and moisture; 3) the changes in the fruit between the time of picking and the time it is in prime eating condition; 4) whether the temperature at which the fruit is kept during ripening has any appreciable effect upon its composition.

Attention is drawn to the fact that if this variety of pear is left on the trees until fully ripe it is of very inferior quality, and very often the inside becomes soft and decayed or coarse and granular. In most sections there is a period of from 6 weeks to over 2 months between the time at which the first commercial picking is made, and the time the fruit becomes ripe. Consequently, there is a possibility of considerable variation in the time at which the fruit may be removed and yet ripen without shrivelling. Hence the advisability of the investigations.

The author gives a survey of the work of former investigators who have studied the chemical composition of pears, and the influence of various environmental factors thereon, and also of the work done in connection with the storage, the effects of temperature and the methods of handling. Apparently the lower the temperature used, down to 31° or 32° *F*, (the lowest storage temperatures used in these experiments), the longer the storage season will be. Most rapid ripening is attained at a temperature of 70°-80°.

The results of all the analyses made by the author and summarised in comparison tables include all the data of fruit from orchards in California, Oregon and Washington. A review of the curves illustrating the development of sugar in the fruit at the various intervals at which pickings were made and the influence of various types of storage upon the sugar content indicates that whereas in the early picked fruit almost all of the sugar is in the form of reducing substances, the increase in reducing sugars in successive lots, as the season progresses, is much less marked than is the increase of sucrose. Pears ripened at 70 °*F* contained the highest percentage of sugar, those at 40° the lowest sugar content, and those at 30° for 6 to 14 weeks and then ripened at room temperature were intermediate in amount of total sugar. There was no marked relation between temperature of storage and relative amount of sucrose and reducing sugar. The percentage of titrable acid tended to decrease in the fruit from the California sections as the season advanced, but to increase in that from Oregon and Washington. There was an increase in acid between the time of picking and the time of full ripening when held at 70°*F*. The acid content of the fruit allowed to become well matured on the tree remained nearly constant during storage.

---

(1) See also *R.* May, 1913, No. 534; *R.* October, 1920, No. 954. (*Ed.*)

There was a progressive reduction in the alcohol insoluble, acid hydrolysing reducing material as the season advanced, both in freshly picked fruit and the same after ripening.

For purposes of dehydration, pears left on the tree as long as possible were found to give not only the greatest tonnage but also the greatest weight of the dried product per pound of green weight.

An examination of the lenticels of the fruit freshly picked showed that if placed in methylene blue solution this readily penetrated the lenticels of the immature early picked fruit, but a brown suberose tissue was formed at the opening of the commercial season which prevented this penetration. This change in lenticels may be a valuable aid to present methods of determining when the fruit is in a condition to pick and handle without danger of shrivelling or wilting.

The percentage of total solids was lowest at the opening of the season and tended to increase with the accumulation of sugar in the late-picked lots.

The advisable conditions of storage are discussed and these are summarised as follows: 1) Use only well developed fruit for storage; 2) put into storage immediately after picking; 3) cool as quickly as possible; 4) maintain an even temperature and hold this down to 28° or 30°*F* if a long period of storage is desired; 5) the cooling capacity of the storage plant should not be overtaxed. With proper precautions of picking, handling and storing, Bartlett pears can be held 2 or 3 months in storage and then taken out in good condition.

218 - **Effect of Temperature on the Resistance to Wounding of Certain Small Fruits and Cherries.** — HAWKINS, L. A., and SANDO, C. E. (Office of Horticultural and Pomological Investigation), in the *United States Department of Agriculture, Bulletin*, No. 830, pp 1-6 Washington, D C, March 6, 1920.

The investigation was undertaken to discover whether small fruits when cooled were less liable to injury than if picked or handled when warm.

The fruits employed were raspberries, blackberries, strawberries and cherries.

Results showed that the average pressure required to puncture berries that had been cooled was considerably more than that required for warm berries. This was found to be the case not only for the freshly picked fruit but also for the berries maintained at ice box temperature (about 16°C) for 24 hours. Washing in tap water did not however apparently increase the resistance of the epidermis to puncture

These results bear out the advantage of picking the berries in the early morning when cool, in spite of the fact that they are frequently wet with dew, as no evidence was obtained that moist berries were more susceptible to injury than dry fruits.

The authors quote the results of experiments by other investigators proving that uninjured fruits are not so liable to decay from fungous infection as those which are injured, and that fruit cooled as soon as possible after harvesting, or picked when cool, are less likely to become infected

219 - **Preservation of Cut Flowers by Refrigeration.** — See No 159 of this *Review*

220 - **Protection of Potatoes from Cold in Transit. Lining and Loading Cars.**— *United States Department of Agriculture, Farmers' Bulletin* 1091, pp 3-27, Figs 22 Washington, D C, Feb, 1920

Recommendations for lining and loading cars for protection of the shipments against cold based upon commercial practices and the results of tests and inspections made by the "Bureau of Markets", supplemented by conferences with those actually engaged in this work Investigations are still in progress

Successful methods are explained concerning the packing in box cars, produce cars, refrigerators and heater cars. The protection from cold depends largely upon a constant current of warm air from the heater directly to the ceiling spreading between the latter and the top potatoes, thence through openings at the opposite ends of the load down to the space beneath the false floor and from under this to the heater again.

During the winter 1917-18 approximately 75 % of all cars prepared to protect potato shipments during the winter were either lined or loaded incorrectly and there was always a danger of overheating the potatoes at the top of the load, and at the same time allowing those on the floor to freeze.

PLANT DISEASES

GENERAL INFORMATION

221 - **The International Convention for the Control of Locusts Concluded in Rome, on October 31, 1920.**

A conference for the purpose of organising the international control of locusts was convoked, under the auspices of the International Institute of Agriculture by the Italian Government with the support of the French Government, and met in Rome, at the said Institute, on October 28, 1920.

The representatives of the following States took part in the proceedings; — Argentina, Belgium, Bulgaria, China, Cuba, Egypt, Spain, French West Africa, Algeria, Indo-China, Madagascar, Morocco, (French zone), Tunis, United Kingdom, Canada, Greece, Hungary, Italy, Erythrea, Italian Somaliland, Tripolitania, Cyrenaica, Mexico, Paraguay, the Kingdom of the Serbo-Croato-Slavonians, and Uruguay.

The conference concluded its labours by drawing up the text of the following Convention, which will bear the fixed date of October 31, 1920: —

Art. 1. — The contracting States pledge themselves to take all necessary measures for the control of locusts that may injure the crops of such neighbouring states as are signatories of the present convention.

Art. 2. — They shall at once take adequate measures to inform the neighbouring signatory States of the movements of locusts under the circumstances mentioned in Art. 1.

Art. 3. — They shall be empowered to make special agreements in their mutual interest as to the common measures to be adopted for facilitating the control of locusts.

Art. 4. — They recognise, from the date of the signing of the present convention, the International Institute of Agriculture, Rome as the International Official Centre for the recording and transmission of all information referring to the control of locusts.

They undertake to furnish to the said Institute, at least once a year, and oftener, if occasion requires, all the information, of a technical, scientific, legislative, and administrative character collected on this subject by competent persons.

The International Institute of Agriculture shall disseminate such information as widely and rapidly as possible.

Art. 5. — Any suggestion emanating from a Contracting State, and dealing with a modification of the present convention, shall be communicated by the said State to the International Institute of Agriculture, and shall be referred by the latter to a meeting of the Delegates of the Contracting parties which shall be convened in Rome by the International Institute of Agriculture, on the occasion of a General Assembly at the said Institute.

The proposals made by the Delegates shall at once be submitted to the approval of the States adhering to the present convention.

Art. 6. — The present convention shall be signed and ratified as soon as possible, and the ratifications shall be consigned to the Italian Government as soon as three at least of the contracting states shall have been able to execute them.

Each ratification shall be communicated by the Italian Government, both to the other contracting States, and to the International Institute of Agriculture.

Art. 7. — Any self-governing State, Dominion, or Colony that has not yet signed the present convention may become an adherent to it on request.

Colonies, on the request of the States of which they are dependencies, are admitted as adherents on the same conditions as sovereign States.

Art. 8. — Their adherence shall be notified through diplomatic channels to the Italian Government, and shall be communicated by the latter to the contracting Governments as well as to the International Institute of Agriculture.

Art. 9. — The present Convention shall come into force, at least as regards the three first States ratifying it, within three months from the date of ratification; and as regards the other States, within six months from the date of the consignment to the Italian Government of the document embodying their ratification or adhesion.

The present Convention has been signed by the plenipotentiaries of the States:— Argentina, Bulgaria, Cuba, France, French West Africa, Algeria, Indo-China, Madagascar, Morocco (French portion), Tunis, Hungary, Italy, Erythrea, Italian Somaliland, Tripolitania, Cyrenaica, Mexico, Kingdom of Serbo-Croato-Slavonians, Uruguay, and Greece.

DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS

222 - **Damage to Plants due to Diseases and Insect Pests in the United States.** — See No. 124 of this *Review*

223 - **Deterioration of Certain Fruit-tree Varieties Caused by Bud Variations.** — See No. 148 of this *Review*.

224 - ***Sclerotinia pseudotuberosa*, the Ascophorous Form of *Rhacodiella Castaneae*, the Cause of Black Rot in Chestnuts** (1). — PEYRONEL, B., in the *Rendiconti delle sedute della Reale Accademia Nazionale dei Lincei, Classe di Scienze, fisiche, matematiche e naturali*, Vol XXIX, Part 10. pp. 324-327, Rome, 1920.

In order to complete what is known concerning the life-cycle of the hyphomycete *Rhacodiella Castaniae* (Bain) Peyr. — considered by the author to be the pathogenic agent of the " black rot " of chestnuts — its perfect form had to be discovered.

---

(1) See *R*, July-August, 1919, No 1042 (*Ed.*)

After many attempts, the author succeeded in obtaining, in October, 1920, a culture of *Rh. castanea*, the ascophorous form of the fungus. It is a discomycete of the family Pezizaceae, being a member of the genus *Sclerotinia* described and identified by the author, at least provisionally, as *Scl. pseudotuberosa* Rehm, found on fallen acorns in Germany (Franconia, Brandenburg), France, and North America.

The author thinks that the morphological differences, especially those of the conidial form, between the acorn *Sclerotinia*, and that found on chestnuts, are to be attributed to an incomplete knowledge of the former, and also to the great polymorphism of the species, especially as regards its vegetative organs.

229 – **Observations made in Italy on the Resistance of Certain Varieties of Peach to Peach Leaf-Curl (*Exoascus deformans*).** — LANDINI, L., in the *Bollettino della R. Societa Toscana di Orticultura*, Year XLV, Nos 9-10, pp 69-70 Florence, September-October, 1920.

The peach-trees in the orchard of the " R. Scuola di Pomologia " at Florence were treated once with a 3 % mixture of Caffaro paste, in 1919, before the buds opened. In 1920, three applications of 3 % and 2 % were made, at intervals of a fortnight, the last being on February 24th, a few days before the buds unfolded. The weather during both these years was favourable to the development of peach leaf-curl (*Exoascus deformans*).

The " Principe di Piemonte " variety obtained from seed by the " R. Scuola di Pomologia " is more resistant then all other kinds. It is a vigorous, free-growing, very productive tree, bearing very large peaches of fine flavour that ripen in September. It remained immune among other infected varieties growing not only on the same piece of ground, but even in the same row. After it, as a resistant variety, comes Morellona (Royal Morillon), of which the leaves were only attacked here and there,. This is followed by " Amsden, " "Tondona Presidente, " " S. Anna, " " Alexander," " Trionfo," late " Poppa di Venere," late " Cresole," and the " Cotogne " varieties, which all proved fairly resistant, especially " Amsden, " which is also one of the best acclimatised peaches. The varieties " Mamie Ross ," " May Flower, " " Regina dei Verzieri, " " Sneed, " " Maddalena Rossa, " "" Surpasse Amsden, " etc., were attacked more strongly. The most susceptible were " Elberta, " " Carman, " " Victor;" " Meraviglia d'ottobre, " " Bella di Georgia, " etc.

As a rule , trees of 8 to 12 years suffered more than younger ones which being less developed, were better aerated and more vigorous.

In order to strengthen the trees most exhausted by the disease, experiments were made in treating them with 2 quintals per hectare, or 200 gm. per tree, of sodium nitrate. Excellent results were obtained, many strong shoots were put forth, which soon entirely covered the branches, and all the fruit ripened perfectly.

From his experiments the author concludes that during years when the trees are much attacked, preventive applications of sprays with a basis of 3 % to 4 % of copper sulphate may check the development of the parasite, even on the most delicate trees, but cannot entirely prevent its appearance On the other hand the more resistant varieties of peach can easily be protected from attack.

230 - **Researchs Carried Out on "Arrabbiaticcio" in Italy.** — MORETTINI, A., in *Le Stazioni sperimentali agrarie italiane*, Vol LIII, Parts 4-5-6, pp. 146-166, Modena, 1920.

The name "Arrabbiaticcio" is given in Italy to the damage that is done to soil when it is worked under unsuitable, damp conditions. The same term is also applied to the abnormal growth of wheat cultivated on "arrabbiato" soil, that is to say, one which is damp on the surface, and dry below. The same condition is also called "guastaticcio" in certain parts of Itly and "terre-gâtée" in France.

The author has tried for ten years — at the Royal Agricultural College of Perousa — to induce this disease artificially either in receptacles filled with soil in pots, or in the field, by mean of mixing soil that is damp on the surface with the underlying dry soil. He however, always obtained negative results, and sometimes the products of the plots where he had tried to cause "arrabbiaticcio" were even better than those of the check plots. The author has thus been forced to discard the hypothesis that the disease is due to working the soil at unsuitable times.

In the many visits he paid to various parts of Umbria, the author was never able to determine whether the land producing "arrabbiato" wheat had been worked under bad conditions,. On the other hand, however he often found, that the withering of the plants was due to unfavourable soil condition, excessive damp, floods, parasitic insects, or fungoid disease. Among the last mentioned, straw blight (*Ophiobolus graminis* Sacc. and *O. herpotrichus* [Fr] Sacc.), is considered characteristic of so-called "arrabbiato" wheat ; in fact, according to the author, by "arrabbiaticcio," and its synonyms, the old agriculturists meant nothing else than the injury caused by the disease now known by the name of straw blight.

231 - ***Ovulariopsis Gossypii*** **n. sp. and** ***O. obclavata*** **n. sp. Fungi found respectively on** ***Gossypium barbadense*** **and** ***Tecoma leucoxylon*****, in the West Indies.** — WAKEFIELD, E M., in *Royal Botanic Gardens, Kew, Bulletin of Miscellaneous Information*, No. 7, pp 235-236, figs 1 London, 1920

Since 1906, a cotton mildew, popularly termed "West Indian Leaf Mildew" was notified in the West Indies. The occasional occurrence of a similar disease has been recorded in Bombay.

The disease occurs on both native and cultivated cotton Leaves attacked by the fungus turn yellow or red in irregular areas, often, at first, bounded by the large leaf veins. Finally the whole leaf is affected, turns yellow and drops off. The under sides of diseased leaves are covered with a white shining mildew, there is also an internal mycelium in the leaf tissues.

Since 1916, the disease has been recorded in varying intensity, but the fungus remained unidentified. Typical specimens of this cotton mildew, found on old leaves of Sea Island Cotton (*Gossypium barbadense*) and, also of a somewhat similar mildew on *Tecoma leucoxylon* were submitted to Kew in 1920 from the Barbados for identification.

Microscopic examination at once showed that both belong technically to the genus *Ovulariopsis* Pat and Har; and the author considers it advisable, for the present at any rate to give these forms distinctive names:— *O. Gossypii*, and *O. obclavata*.

232 - ***Ganoderma applanatum* (*Polyporaceae*). Injurious to the Oil Palm (*Elaeis guineensis*) in the Island of São-Thomé, Gulf of Guinea.**— MAUBLANC, A and NAVEL, H C, in *L'Agronomie coloniale*, Year IV, No, 30, pp 187-101 + 1 Plate Laval, Paris, 1920.

This disease, characterised by the rotting of the base of the trunk, has spread considerably in the plantations of oil palm (*Elaeis guineensis*) situated in the lowlying parts of the North east region of the Island of São-Thomé. This rotting is followed by the formation of a large cavity occupying as much as a third or half of the base o the trunk, and, especially if the palm has attained a considerable height (10 metres or over) causing its fall after a certain time, without, however altering the appearance of the foliage, or interfering with the production of the fruit until the very last.

The examination of numerous individuals of *E guineensis* has shown that the diseased trees bear on their base, and usually to a height of 1 metre, the fructifications of *Ganoderma applanatum* Pers In the Island of São Thomé, this fungus only attacks the oil-palm, further, it is certain that its presence always precedes the rotting of the trunk. It is therefore reasonable to attribute the disease of the palm to the parasitic polyporacea, and the destructive action of its mycelium upon the tissues of the trunk.

The first precautionary measures necessary to arrest the course of the disease, is to burn all fallen individuals of *Elaeis*. It is also necessary, in plantations, where the disease has been observed, to examine all the palms with great care. The fungus fructifications, and all the diseased tissues should be removed carefully from all the trees attacked, a portion of the healthy part being cut away at the same time After burning the débris, it is advisable to disinfect the wounds, applying, for instance, a concentrated solution of sulphate of iron and to cover them with a coating of tar. It is also advisable to stop up the cavities in the stipe with a resistant substance such as cement, in order to render it more solid and to prevent its breaking.

233 - ***Cucurbitaria naucosa*, an Ascomycete Parasitic on *Ulmus montana* in the Canton of Vaud, Switzerland.** — MORELLON, M., in the *Journal forestier suisse*, Year LXXI, No. 8, pp 155-157, Berne, 1920

At Montcheraud (Canton of Vaud), peculiar swellings appeared in 1912 followed by the withering of the branches upon the upper surfaces of the lower branches of certain elms (*Ulmus montana*) planted in 1902.

This affection was observed every year at the beginning of July, and in that month in 1914, one of the trees lost all its leaves ; it was pruned on the following August 1, and finally died in 1919

The other individuals of *Ulmus montana* withered in a similar manner.

Of recent years, these trees have been visited by a large number of formicides (*Lasius marginatus* or *L. fuliginosus*). In September, 1919, a quantity of dead aphids (*Tetraneura ulma*) were found lying at the foot of one of the elms; the leaves of the tree being covered with galls produced by this insect.

An examination made of the infected branches by Dr. D. CRUCHET during 1919 and 1920, revealed the presence of Sphaeriacea, *Cucurbitaria naucosa*. Fries, and of its metagenetic forms *Diplodia melanea* Lév., and *Camarosporium cruciatum* (Fuckel) Sacc.

A further examination of infected individuals of *U. Montana* led to the discovery in the cankers, and occasionally at the base of the last year's branches, of the scale-insect *Gossyparia ulmi*, whereas the young 1920 shoots were already attacked by *Cuc. naucosa*. It is thus quite clear that the mischief is caused by the fungus. The scale-insects only establish themselves where there is abundant sap, namely where a pad of callus covering a wound is in course of formation.

The only practical way to prevent the spread of the fungus would be to burn the diseased branches, but such a proceeding might lead to the disappearance of a forest tree that is already rare in the district in question.

234 - ***Hypoderma pinicola* and *H. strobilicola*, Discomycetes injurious respectively to *Pinus sylvestris* and *P. Strobus* var. *nana*, in Scotland.** — WILSON, M., in *Transactions of the Royal Scottish Arboricultural Society* Vol. XXXIV, Pt. 2, pp. 222-223 Edinburgh, Nov 1920

Specimens of Scotch fir (*Pinus sylvestris*) showing defoliation and discoloration of the needles, were collected near Dalmally in September, 1920. At the first glance, there was no obvious sign of attack by a fungus, but subsequent investigation has proved that the damage is due to a fungus which has been provisionaly identified as *Hypoderma pinicola*, Brunch. This discomycete was discovered in Norway in 1892 and was later recorded in Denmark and Germany. In the Scottish specimens, brownish or yellowish-grey areas were noticed on the needles, and the abundance of these areas gives the whole shoot a greyish tinge. Examination of the discoloured areas with a lens reveals minute slits in the epidermis from which exude drops of resin. On soaking in water, the slits, which are found in series in both surfaces of the leaf, open widely and reveal the elongated fructifications of the fungus.

BRUNCHORST states that the disease attacks the young neeedles immediately after their development; after one year the discoloration appears, the fructifications of the fungus mature in July and the needles fall in the autumn or winter of the second year. LIND, in Denmark, states that the disease is particularly prevalent during cold and wet summers.

Specimens of the fungus have been collected from other localities in Scotland, and it appears that the disease is widespread; considerable damage is being done by the extensive defoliation of the shoots.

H. strobilicola, Rostr., a closely allied species, was found during April, 1920, at Murthly, causing defoliation of a specimen tree of *Pinus Strobus* var. *nana*. On the Continent this species causes considerable damage to *P. Strobus* but it had not been previously recorded in Scotland.

INJURIOUS INSECTS AND OTHER LOWER ANIMALS

235 - **Varieties of *Vigna sinensis* Resistant to *Heterodera radicicola*, in the United States.** — See No 144 of this *Review*.

236 - ***Sesamia nonagrioides*, Macrolepidopteron injurious to the Sugar Cane and Other Gramineae.** — See No 158 of this *Review*.

237 - **Notes on the Coleopteron *Otiorrynchus sulcatus* and the Hymenopteron *Hoplisus laticinctus*, Parasitic on *Begonia tuberosa*, in France.** — FLAMARY, A., in the *Comptes rendus des séances de l'Académie d'Agriculture de France*, Vol. VII, No 2 (Meeting of Jan. 12, 1921), pp. 53-56 Paris, 1921

On May 26, 1919, the author noticed a tuber of *Begonia tuberosa*, grown in a pot, almost completely eaten away internally by about 40 small white larvae. Round the decayed material, he also noticed a number of brown cocoons.

The soil from the pot together with the larvae and cocoons was placed in a glass jar, moistened with rain water, and the jar was covered with fine muslin.

After pupation a number of coleoptera identified as *Otiorrhynchus sulcatus* emerged on June 25.

The females of *Hoplisus laticinctus* emerged from the brown cocoons on June 30, and the males of the same species from July 3 to 7. The number of males was small compared with that of the females.

238 - ***Galerucella nymphaeae* Coleopteron injurious to *Nymphaea advena (Nuphar advena)* in New Jersey.** — WEISS, H. B. and WEST E., in *The Canadian Entomologist*, Vol LII, No. 10, pp. 237-239. London, Oct., 1922.

This species occurs throughout New Jersey on the yellow pond lily *Nymphaea advena* Ait (*Nuphar advena*), which is common along the lower Delaware River and adjacent ditches and tide water streams. During the seasons 1919 and 1920, it was particularly abundant at Monmouth Junction, Westville, and several other places in New Jersey, defacing the leaves and flowers of the last plant.

Notes on the biological formation of the insect are given, drawn for the most part from preceding work on the subject, the description of the egg, larva, pupa and adult has already been made by MACGILLIVRAY and the author here adds further notes.

Preceding investigations have brought into evidence the fact that arsenicals are quite effective remedies in checking this beetle.

239 - ***Silvestrina silvestrii* var. *cecconiana*, n. var. Dipteron Parasitic on Olive Trees in Italy.** — KIEFTER J J, in *Bulletin de la Societe entomologique de France*, No 17, pp. 296-297 Paris, 1920

Systematic description of *Silvestrina silvestrii* var. *cecconiana*. This dipteron has been notified in Italy by Prof. G. CECCONI. This species originates in South Africa and Brazil; it has been obtained from branches of *Morus alba* attacked by *Diaspis* (Capetown and São Paulo) and from fruits of *O. verrucosa* (Natal).

240 - ***Gracilaria perseae* n. sp. Microlepidopteron Injurious to Avocado (*Persea gratissima*) in Florida.** — BUSCK, A, in *The Canadian Entomologist*, Vol LII, No 10, pp 239, fig 1. London, Oct, 1920

Morphological description of the New species *Gracilaria perseae*, bred from leaves of avocado (*Persea gratissima*) at Miami, Florida, during July by G. F. MOZNETTE who states that the species is seriously destructive to the young growth.

The larvae make a small mine between the veins of the young leaves ans subsequently fold the tip or the sides of the leaves downwards. The cocoon is white, narrow, oblong, and is spun in a fold on the leaf of the host plant.

241 - ***Pemphigus populi-transversus*, Aphis Parasitic on the Poplar and on Several Crucifers in New Zealand.** — MILLER, D., in *The New Zealand Journal of Agriculture*, Vol. XXI, No. 3, pp. 134-135, figs 2. Wellington, Sept 20, 1920.

In March 1920, in central Otago, leaves of the poplar were collected with petioles possessing characteristic galls, produced by the aphis *Pemphigus populi-transversus* Riley, a species frequently seen on the poplars in North America.

This insect is interesting from the agricultural standpoint in that it does not confine its attacks solely to poplars; but during migration it is parasitic on the roots of both cultivated, and wild crucifers. It does not usually cause any noticeable damage, but the loss involved may become important if the infested area is extended.

242 - **Antiscorbutic Action of Raw Potatoes, Whether Whole or Crushed** (1). — BEZSSONOFF, in the *Comptes rendus de l'Académie des Sciences*, Vol CLXXII, No 1, pp 92-94 Paris, January 3, 1921

Seeing how important a place is occupied by the potato in the human dietary, the author thought it would be useful to obtain some data as to the content of antiscorbutic principles present in this tuber. To this end, he studied the antiscorbutic effect of raw, unpeeled potatoes upon guinea-pigs fed on oats and water He also compared the antiscorbutic effect of a given quantity of raw, whole potatoes with that of the same amount crushed in a hydraulic press ; the juice and pomace being at once fed to a guinea-pig. He further proposed to determine the antiscorbutic action of these two fractions taken separately.

These experiments showed that the antiscorbutic action of the whole potato (used young, while the pulp is yellow, and before the development of the green cortex) was equal to that of plants with well-marked antiscorbutic properties, such as the cabbage and dandelion

Used in equal quantities, crushed potatoes are much less efficacious than entire tubers

The juice extracted by pressure from raw potatoes has a certain antiscorbutic action, but much less than the same amount of whole, uncrushed tubers.

The pomace alone appears to be almost useless. If the pomace obtained by crushing raw potatoes be added to the juice extracted by the same operation, the antiscorbutic action of the latter is not appreciably increased.

October, 1920.

I. TECHNIQUE OF FIELD EXPERIMENTS. — The author attributes great importance to the use of the calculation of the probable error in improving the technique of field experiments. The present technique is not sufficient for the examination of the capacities of numerous varieties, where it is necessary to determine slight differences; in fact, the average error in the field, in the case of fertilisers and varieties, in spite of every care, is from 5 to 7 %, whereas it should not exceed 3 %. Countless mistakes are made even in sowing, and these errors vary according to the character of the seed and the manner of sowing it.

In the case of plots, the experiments of MONTGOMERY, MERCER, HALL, and LARSEN did not give concordant results.

As regards the area of the plots, it was found that the accuracy increased with their size, whereas TOULAIKOV, WOOD and STRATTON were convinced that the error is independent of the size of the plot. But here the question is united to that of the division of the plots into, the different groups composing the "Einzelbeobachtungen" (1). The author believes that when the experiment is repeated on more than 6 plots it does not contribute to any important extent to the accuracy of the "Einzelbeobachtung."

For each of these the error is given by the formula

$$\sqrt{\frac{\Sigma a^2}{n}}$$

where Σ represents the ordinary sign of totalisation, and *a* the elementary errors, that is to say, the differences between the value of the plot and the mean value of the "Einzelbeobachtung," and *n* the number of plots subjected to the "Einzelbeobachtung."

---

(1) The "Einzelbeobachtung" (lit. individual observation) includes the data respecting the groups of plots treated alike, or all the values of the plots, each of which is affected by its own elementary error.

After making a comparison between 3 different systems of arranging the plots, each carried out with 12 square plots in one, two, or three regular lines, it was found that the most accurate results were obtained when the plots were arranged in 2 lines only. Repetition contributed more to exactness than did the size of the plots (1).

II. CALCULATION OF THE COMPENSATION IN EXPERIMENTS ON SOIL CULTIVATION. — These experiments bore chiefly on forest trees. The deduction relating to the minimum number of observations necessary for determining a mean error, which is a datum of great importance in estimating the accuracy and the test value, is of paramount importance, both from the forestry and the agricultural standpoint. The author believes that the accuracy of the mean value is proportionate, and depends only on the number of the observations, not on the size of the error of the mean value.

In forestry determinations, a mean value of any real importance must be deduced from at least 50 to 60 individual observations.

III. — EXPERIMENTS ON THE SIZE OF THE PLOTS. — The use of the theory of probabilities in testing the accuracy of field experiments is of quite recent date. The object of the authors is to establish the crops (expressed in terms of a hectare) borne by plots of different sizes and arrangement, and to determine the importance of the application of the theory of probabilities in testing the results of the experiments carried out in the plots when these data have been converted, and expressed in terms of areas that are of appreciable practical size.

The experiments were carried out on a piece of very uniform, flat land belonging to the Station of Lauchstädt; the area of the plots, whether separate or contiguous, was from 200, 100, or 9 sq. m. each, the first being rectangular, and the second and third square. In 1913, sugar-beets were grown in them, in 1914 and 1915, winter wheat was cultivated, in 1916 and 1917, they were under barley. The results were as follows:—

1) The plots separated from one another, in accordance with PFEIFFER's advice, by strips of uncultivated ground, 80 cm. wide, did not yield satisfactory results, either because the yield per hectare was too high (the smaller the plot the higher was this yield), or because the fertiliser, partly owing to the heavy crop, had much less effect.

2) The yield of the contiguous plots of 9, 100 and 200 sq. m. when converted and expressed in terms of a hectare, gave more uniform data, especially when liberally manured, so as to compensate for differences in the soil conditions. The increases in the crops obtained by manuring plots of different size are not such as to guarantee sufficient agreement in the results.

3) The application of a fertiliser to a plot has no particular effect on the contiguous plot, if it is spread in such a manner that its external limit falls within the last line of the plants sown on the manured plot.

4) The differences between the largest and smallest crop for each

---

(1) DAY has carried out similar experiments. See *R.*, Sept., 1920, No. 831. (*Ed.*)

group of plots, when expressed in terms of a hectare, vary in inverse proportion to the size of the plots.

The authors subsequently estimate the results from a calculation of the probabilities, subtracting the amount of the probable deviation from the arithmetical mean by employing the formula (1) $\sqrt{\frac{\Sigma^2}{n\,(n-1)}}$ and conclude from this, that:

5) The calculation of the probabilities allows it to be foreseen that the results of the experiments are very certain, expecially in cases where the fertiliser produces large increases in the yield, because these increases usually represent a considerable multiple of the probable error. But in all such cases, the increases are so high and concordant, that there is no doubt as to their accuracy, and it is unnecessary to have recourse to the theory of probabilities. For this reason, the results of experiments should be regarded with suspicion, when a fertiliser produces but light increases in the yield. If in such cases, however, the experiments were repeated on a large number of plots of different dimensions, the incertitude would not be removed, in spite of the calculation of probabilities. The same occurs where experiments are carried out for several years on the same plots. If every year, from the average of the various separate experiments, any effect, however small, is obtained from the application of a nitrogenous fertiliser, this effect must be regarded as real, whatever results may be obtained from the calculation of probabilities.

In spite of the certainty apparently conferred by this theory upon the results obtained from experiments on plots of the same size, the increased crops produced by the fertiliser on plots of various dimensions do not agree sufficiently from many points of view But the calculation of probabilities would not be able to show which data are most accurate, nor whether the variations in yield are due to differences in the character of the soil, or to other causes.

IV. RELATION BETWEEN THE SIZE OF THE PLOTS AND THE ERROR IN THE "EINZELBEOABACHTUNG" IN FIELD EXPERIMENTS. — Experiment plots of 25 sq. m under rye and oats, of 7 5 sq. m. under potatoes, and of 5 sq m. under turnips, and combinations of the same plots, so as to obtain multiples of these areas.

The different results of the experiments gave very irregular variations with the characters of fortuitous errors.

If the size of the plots be brought up to 50 sq. m., the error, in the case of cereals, is considerably reduced.

The true error, as well as the probable error which results from it, decreases with the increase in the size of the plot.

V. MITSCHERLICH'S COMPENSATION CALCULATION FOR THE ELIMINATION OF SOIL DIFFERENCES IN FIELD EXPERIMENTS. — RODEWALD severely criticises the compensation method proposed and adopted by

---

(1) See MITSCHERLICH · *Bodenkunde fur Land- und Forstwirte*. Berlin, 1913, p. 304. (*Ed.*)

Mitscherlich is his work entitled "Feldbauversuche mit Kartoffeln" (Field Experiments with potatoes).

Mitscherlich's method is applied to Wagner's quadruple experiment of five-plot manuring, that is to say, to 20 plots that have been subjected to 4 similar experiments with fertilisers of 5 different formulas (1st., no fertiliser, 2nd., K + N, 3rd., K + P, 4th., N + P, 5th. complete fertiliser) (1). Mitscherlich starts from the point that the sum of the crops from the combination of the 5 differently manured plots, no matter where they are taken, must be constant if the soil is uniform. If there is any difference in the figures, this is due to the varying fertility of the soil and the yields must be adjusted to the mean value of this sum, by expressing them in percentage values of the mean value. The author, however, after comparing the data obtained by Mitcherlich's method with those given by the ordinary method of the arithmetical mean, concludes that the former are erroneous, and that the usual method is more suitable for compensation and determining average yields, as well as for calculating errors.

Finally, the author suggests his own method of calculating systematic errors due to variations in soil fertility, taking as his starting-point the following premises: —

1) The observer shall base the calculation on the relative action of the fertiliser and, consequently, express the yield of each plot as a function of the relation between the actual yield on any plot examined and the yield of the unmanured plot, making part of the same fertilising experiment (1st, 2nd, 3rd, or 4th) and taken as a unit of measure.

2) Consider the unfertilised plots as free from error. This, according to the author, is certainly not quite accurate, but the error cannot be estimated by the above-mentioned experimental method. In order to estimate such errors it is necessary to include in the experiment plan from the beginning, at least 2 successive unfertilised plots in every fertilisation experiment, and then to bring up the yield of the fertilised plots to the average of the non fertilised ones of the same experiment.

244 - Practical Universality of Field Heterogeneity as a Factor Influencing Plot Yields.

— Harris, G. A. (Office of Western Irrigation Agriculture, Bureau of Plant Industry, United States Department of Agriculture), in the *Journal of Agricultural Research*, Vol. XIX, No. 7, pp. 279-314. Tables 3, bibliogr. of 22 works. Washington, D. C., July 1, 1920.

The results of studies with reference to the use of modern higher statistical methods in the analysis of data concerning the actual yields of test plots. The particular phase of the problem dealt with is the lack of uniformity of the experimental field, and the author considers it worth while to ascertain to what extent results derived from methods now in use, may be considered reliable.

Heterogeneity is defined as differences in capacity for crop production throughout the field of such a magnitude as to influence in a similar way, but not necessarily to a like degree, the yield of adjacent small plots, and it is pointed out that this factor is measured by a coefficient which shows the degree of correlations between the yields of associated ultimate plots, grouped in combination plots This coefficient has been determined for a relatively large series of experimental fields widely distributed throughout the world, and planted with a considerable variety of crops; the results show that in every field the irregularities of the substratum were sufficient to influence the experimental results, often to a marked extent. The records are in a large part drawn from the writings of those who are recognised authorities in agricultural experimentation, and who have given their assurance of the suitability of the fields upon which the tests were made. Nothing could more emphasise the need of a scientific criterion for substratum homogeneity than the fact that correlations between the yields of adjacent plots ranging from $r = + 0.02$ to $r = + 0.83$, can be deduced from the data of fields which have passed trained eyes as satisfactorily uniform.

---

(1) See: Mitscherlich, *loc. cit.*, p. 239. (*Ed.*)

A second phase of this investigation has been to ascertain whether the physical or chemical requisites for plant growth are so distributed over experimental fields thas they may be reasonably looked upon as the source of demonstrated homogeneity in yield. The heterogeneity coefficients for percentage of water content and for chemical composition of the soil were found to be of the same order as those determined for crop yields, and the belief has been expressed that this heterogeneity is directly due to these and other physical and chemical factors. The existence of significant heterogeneity in fields passed by experts as satisfactorily uniform, according to the author, illustrate the inadequacy of personal judgment concerning the uniformily in physical characters or in crop-producing capacity of fields under consideration for experimental work.

This demonstrates the need for greater care in agronomic technique and a more extensive use of the statistical method in the analysis of the data of plot trials, if they are to be of value in the solution of agricultural problems.

CROPS AND CULTIVATION

245 - **Development of Agricultural Meteorology in the United States.** — WARREN SMITH, J., in *Monthly Weather Review*, Vol 48, No. 5, pp. 281-283, bibliogr. of 46 works. Washington, May 1920.

For a considerable number of years now, the problem of Agricultural Meteorology has attracted the attention of American agronomists; in 1806 the Hon. Simeon DE WITT of Albany read a memoir on "Climate and its Relation to Agriculture" before the American Agricultural Society in New York City. In April, 1817, JOSIAH MEIGS, Commissioner of the General Land Office, issued a circular soliciting meteorological records, and in 1819 the Surgeon-General of the army established a system of meteorological observations at the Army posts. This led the Military Academies to interest themselves in the question, thus, in 1825, the regents of the University of the State of New York directed that meteorological observations be made at each of the Academies under their supervision, and, in 1837, the Franklin Institute and the State of Pennsylvania followed the same lines.

The present U. S. Weather Bureau was inaugurated by an act of Congress on February 9, 1870, authorising the Secretary of War to organise a meteorological service throughout the United States.

The Iowa Weather Service, was established in 1875; the Nebraska Service in 1878, the Missouri Service in 1877, and the Ohio Service in 1882.

By 1891 a special weather and crop service was in operation in nearly every State; the publication of Weather and Crop Bulletins was already started in 1887.

On July 1, 1891, all the meteorological work of the Signal Service was transferred to the Department of Agriculture and the present United States Weather Bureau was put into operation. Since this transfer, the work of the Weather Bureau in its relation to Agriculture has developed steadily, and special services have been established for the direct benefit of areas devoted to maize and wheat, cotton, sugar and rice, cattle, tobacco and fruit.

Special forecast and warning services have been inaugurated for tobacco, fruit and truck growers; alfalfa and rice harvesting; fruit spraying, alfalfa seed harvest and sheep shearing etc.

The present Division of Agricultural Meteorology was established as a new division in the Weather Bureau on February 23, 1916. The National Weather and Crop Bulletin has been developed to show the effect weekly upon growing crops, and studies are being made to find the most critical period of growth of the various crops and the weather most affecting them. Detailed temperature and moisture surveys are being carried on in citrus and deciduous orchards to determine the distribution of damaging weather factors, the effect of orchard heating on the temperature, and the part that radiation plays in temperature variations and fruit protection.

Valuable studies in the forecasting of minimum temperatures have been published and equations evaluated from the knowledge of the moisture in the atmosphere in the afternoon and its relation to the temperature variations during the following night (1).

246 - **Apparatus for Protection from Frost in the United States.** — KIMBALL, H. H., and YOUNG, F D, in *Monthly Weather Review*, Vol. 48. No. 8, pp 461-462. Washington, Aug. 1920.

There are 3 quite different types of oil burning heaters in general use on the Pacific Coast.

1) High stack heater, with an abundant draught, resulting in almost complete combustion of the oil, and the formation of only light smoke;

2) Lard-pail heater, with insufficient draft for complete combustion and a dense smoke.

---

(1) See *R.* Oct. 1920, No. 950. (*Ed.*)

3) Short-stack heater, intermediate.

Which of these 3 types is to be preferred? The experiments conducted at the Stations of Pomona, Cal. and at Medford, Oreg. are very interesting in this respect. The results obtained may be summarised as follows: —

1) The presence of a dense smoke cloud diminished nocturnal radiation on a average about 0.011 calories per minute per sq. cm. of surface, with maximum effects of nearly 0.030 calories.

2) At a distance of 10 ft., the intensity of radiation from a lard pail heater is about 0.080 calories per minute per sq. cm.; from a short stack, about 0.100 calories; from a high stack, 0.300 calories.

3) Since the intensity of radiation varies inversely as the square of the distance from the source of heat, at a distance of 15 ft. from the heaters it will be less than half at 20 ft. *i. e.* about $^1/_4$ that given above.

4) The heating by radiation is in addition to the heating by conduction and convection of hot air and gases from the burning oil in its immediate vicinity.

It may therefore be concluded that the retardation of nocturnal radiation by the smoke cloud plays an insignificant part in frost protection. The important point is the heat which emanates directly from the radiators; high stack heaters may therefore be recommended. These possess the advantage of avoiding the production of dense smoke clouds which might prove decidedly disagreable is a populated area.

247 - **Evidence of Climatic Effects in the Annual Rings of Trees** (1). — DOUGLASS, A. E. (University of Arizona, Tucson), in *Ecology*, Vol I, No 1, pp 24-32, figs 10, Brooklyn, N. Y Jan 1920

The author presents an entirely new conception towards the relation between climate and tree growth in that it recognises that factors other than seasonal rainfall influence the size of the trees' annual rings.

The information given is in connection with the process of dating and measuring about 85 000 annual rings which had grown in some 275 different trees in the States of Oregon, California, Arizona, Colorado and Vermont, as well as in England, Norway, Sweden, Germany and Bohemia. The climatic evidence is of 3 kinds: — 1) The direct correlation between the annual rings of yellow pine (*Pinus ponderosa*) and the rainfall at Prescott, Arizona; — 2) The marked resemblance found in certain individual rings over a wide extent of the country in which climate is the only common factor; — 3) An extension of the last mentioned evidence but instead of merely taking into account similarities in individual rings, similarity in ring variation over large areas are also considered, by a form of harmonic analysis. The author therefore, constructed an instrument called a periodograph capable of analysing plotted curves into their component cycles, if such exist.

The results obtained with sequoias and yellow pines encourage belief in the reality of this kind of analysis and at the same time to regard climate as a very important if not controlling, factor

---

(1) See *R.* Oct-Dec. 1919, No 1081. (*Ed.*)

The author concludes from analyses already made that: 1) Trees probably integrate, and may be made to reveal climatic combinations advantageous to certain types of vegetation; 2) The study of this subject promises to enable the outlining of so-called agro-meteorological districts, that is, areas over which exist similar advantageous combinations of weather elements; 3) The application of the criterion of mean sensitivity promises to make possible the proper selection of sequoia records, which in turn will give much climatic information about the last 3200 years.

248 - **Effect of Heat and Drought on Eucalyptus Plants.** — See No. 303 of this *Review*.

249 - **Humidity and Pore Space, Factors Determining the Adaptibility of the Soil to Tillage.** — ZANDER, H (Landwirtschaftliches Institut der Universitat Königsberg, i. Pr. Abteilung fur Pflanzenbau), in the *Internationale Mitteilungen fur Bodenkunde*, Vol. X, Parts 3-4, pp 79-117, figs 6, Graphs 3, Tables 2. Berlin, 1920.

The greater or less facility with which soil can be worked has been investigated by Messrs MEYER, SCHULLER, HABERLANDT, PUCHNER, VON PIEDZICKI, SCHMERBECK, VÖLCKER, and SPRENGEL, but no practical results were obtained because, according to MITSCHERLICH, this problem, which is of the greatest importance for agriculture, has so far never been studied in a systematic manner, *i. e.* the question of tillage has not been considered as a function of the volume of the pore space in the soil, of the water content, and of the physical condition of the solid soil particles. MITCHERLICH believes that the dynamometer is at present the sole means of determining whether a soil is in a condition to be worked.

The author has tried to determine in the laboratory the laws governing this condition, because only in the laboratory can sources of error be eliminated, and the variable factors isolated.

The apparatus used was MITSCHERLICH'S automatic digger (1) as modified by the author by means of the addition of a closing apparatus at the top with a moveable support regulated by screws, and furnished with a system of wheels round which a rope is wound. The rope is attached on one side to a handle and on the other to the chassis to which the lever percussion-hammer is fixed that hits the handle of the spade in order to drive it into the soil; the height from which the hammer falls, and the number of its blows supply the mechanical force required to make the blade penetrate into the ground, and furnishes an indication of the suitability of the soil for tillage. The apparatus is provided with accessory parts for keeping the hammer vertical and eliminating errors such as friction.

The experiments were carried out by placing the automatic digger on wooden boxes or iron cylinders containing the different soils to be studied, which could easily be weighed and tested; sand, clay, garden-mould, and peat from a " high-moor " (Hochmoor) were used. The soil was first freed from stones, and then pressed down in the boxes or cylinders, moistened, and levelled. The hygroscopicity, moisture, specific and absolute weight, and the volume of the soil were determined each time. By keeping the total pore space constant, and varying the humidity of the soil, the author determined experimentally for each soil some pairs of values relating to the humidity of the soil, and the corresponding mechanical work necessary to drive the spade into it. A being the mechanical work expressed in *erg*, and x the degree of humidity in volume, the author, after deducting the hygroscopic water and observing the course of the curve obtained was able to establish the exponent:—

---

(1) Cf. E. A. MITSCHERLICH, *Bodenkunde fur Land- und Forstwirte*. Parey, Berlin, 1913, p. 85. (*Ed.*)

$$A = \frac{a \quad \tau^{\varepsilon}}{c^{hx}}$$

where a and b are constants, log e 0.4343, and ε is the external surface of friction, as long as the humidity of the soil remains below the hygroscopic water, after which, the hygroscopicity being exceeded, the exponent becomes equal to + 1. For a soil with a given pore space, it suffices to determine experimentally a pair of values for two degrees of humidity and the corresponding mechanical work, in order to obtain the constants of the exponent of the water curve (" Wasserkurve ").

The adaptability of the soil to tillage is more affected by the pore space than by moisture. The author, after having also made experiments in this connection with the same apparatus, keeping the humidity constant, and varying x the contraction of the volume of the pores, found that the work of penetration y, and consequently the volumetric curve " Hohlraumvolumenkurve ") may be expressed by the logarithmic function

$$\nu = \frac{a}{k_{\tau}} + r$$

With the help of these two functions, and having already determined by experiment, as has been said, some pairs of values for the water-curve and the volumetric curve, it is possible to calculate tables for each soil. In these tables, the upper horizontal line gives the amount of humidity, the vertical left-hand column indicates, in the same manner, the contraction of the volume of the pores: the mechanical labour corresponding to a given humidity, and to a given size of the volume of the pores will therefore be found, as in the multiplication table, at the vertical and horizontal intersection of the relative lines

On the other hand, once the humidity and the mechanical work are known, these tables can show the volume of the empty spaces, which, according to the author, is a surer and easier method of determining the volume of the pores; he compares it with the earlier methods adopted by TRUKA and KOPECKY, the results of which are very similar (1).

In order still further to demonstrate the accuracy of his method, the author quotes the results obtained by MARQIUS, and finishes by saying that the conclusion resulting from his experiments will be of great importance for practical agriculture, since the least work is needed for tilling the soil when the water present in the ground is not more or less than the hygroscopic water, irrespective of the volume of the pores, and of other physical conditions.

---

(1) See *R.*, 1912, No. 1067. (*Ed*)

250 - **The Moisture Equivalent in Relation to the Mechanical Analysis of Soil.** — MIDDLETON, H. E (Soil Physical Investigations, Bureau of Soils, United States Department of Agriculture), in *Soil Science*, Vol. IX, No 2, pp. 159-167. Tables 3, Bibliogr. of 4 works. Baltimore MD., February 1920.

The objects of the present investigation were to determine whether or not the moisture equivalent (1) could be used as a basis to assist in the classifications of soils, and what relation, if any, existed between the moisture equivalent and the mechanical analysis.

The apparatus employed consisted of a metal cylinder attached to the shaft of a vertically mounted electric motor, and holding 16 soil boxes provided with wire gauze bottoms permitting the escape of the excess moisture. A total of 172 duplicate determinations were made on samples from various districts.

From the results obtained, it was evident that the moisture equivalent may not be used as a basis for the classification of soils, but may be of valuable assistance in the interpretation of mechanical analysis. There is a direct relationship between the moisture equivalent and the percentages of sand, silt and clay in the soil as determined by mechanical analysis. This relation may be expressed as:

$$0.063 \text{ sand} + 0.291 \text{ silt} + 0.426 \text{ clay} = \text{moisture equivalent.}$$

The presence of considerable amounts of organic matter in the soil tends to increase the moisture equivalent and to disturb the relation between the mechanical analysis and the said equivalent.

251 - **Effect of Oxidation of Sulphur in Soils (2) on the Solubility of Rock Phosphate and on Nitrification.** — SHEDD, O. M (Chemist, Kentucky Agricultural Experiment Station) in *The Journal of Agricultural Research*. Vol. XVIII, No. 6, pp. 329-345, Tables 14. Bibliogr. of 14 works. Washington, D. C., Dec. 15, 1919.

A continuation of previous work on the sulphur content of Kentucky soils, and the effect of this element and its compounds on plant growth, when it was found that comparatively large amounts of added sulphur are easily oxidised to sulphate in the soil (3). The results also indicated that the sulphuric acid formed would act on rock phosphate when present and convert it into a water soluble form.

The following materials were used in the experiments now undertaken: —

Rock phosphate (Tennessee brown rock) containing 14.2% phosphorus and guaranteed 95 % to pass a 100 mesh sieve; sulphur (ground brimstone or crude sulphur); soil, (fertile bluegrass soil with a high phosphorous content); manure (partly rotted horse manure, fairly free from straw). The starter was simply a mixture of soil, rock phosphate and sulphur, in which the sulphofying organisms were numerous and active. The determinations made included acidity, water-soluble phosphorus, ammonium-citrate soluble phosphorus, total phosphorous, sulphates, nitrites, nitrates, total nitrogen and moisture.

---

(2) See *R.*, March, 1918, No. 264. (*Ed.*)

(3) See *R.*, Sept., 1918, No. 961 and *R.*, Jan., 1919, No. 24. (*Ed.*)

After 24 months time, about 17 and 84 % of the total phosphorous had been converted into a water-soluble and ammonium-citrate soluble form, respectively

Sulphurisation did not proceed as rapidly as when the inoculation was made with the sulphofying organism, when the time was reduced nearly one-third.

Composts prepared under the same conditions but omitting the sulphur also showed favourable results in rendering the soil phosphate or that added in rock sulphate soluble, but not to the same extent as when sulphur was present.

Nitrification was found to proceed to a certain extent, regardless of the acid formed by the sulphur oxidation. The amounts of nitrogen found to be nitrified amounted to approximately 20 % of the total originally present.

Experiments were conducted to determine the sulphofying powers of different types of soils which were later used in compost experiments. When 25 and 50 mgm. of sulphur were added to 100 gm. of soil, about the same percentage of the total was oxidised in a given time. In all experiments the barium sulphate was treated with hydrofluoric acid and reprecipitated from sulphuric acid to purify the precipitate

Inoculation of mixtures of rock phosphate and sulphur was not sufficient to promote rapid sulphurisation Soil or soil water were additional necessities. The Fayette County sample showed the highest capacity to render phosphate soluble when mixed with rock phosphate and sulphur. That the production of soluble phosphate was caused by the presence of sulphuric acid generated by the oxidation of the sulphur was demonstrated by the parallel rise in acidity and sulphate.

The author considers that the best conditions to promote the reaction are initial inoculation, high temperature, thorough aeration, and a fair moisture content.

Other contributory factors are the proportions of the different ingredients and probably their mass. Taking into account the cost of materials, the compost consisting of soil, manure, rock phosphate and sulphur appears to be the best, and the presence of some manure and more soil would be advantageous to provide a means of increased bacterial action as well as assisting in the maintenance of the moisture content.

The acid phosphate made by this procedure had just as good a physical condition as the commercial product in spite of the possible objections to time and labour involved. However, as better methods of inoculation are developed, the process may be simplified and it may become of immediate practical benefit.

[251]

252 - **Ammonification of Manure in Soil.** — I. BRIGHT, J. W., What Soil Organisms take part in the Ammonification of Manure. — II. CONN, H. J., Taxonomic Study of two Important Soil Ammonifiers, in the *New York Agricultural Experiment Station, Technical Bulletin*, No. 67, pp. 3-45, Tables 13, Bibliogr. of 43 works. Geneva, N. Y., April 1919.

Former investigators suggest that the spore forming organisms are responsible for soil ammonification (1), but on the basis of the data obtained from the author's experiments, there seems to be good evidence that the rapidly liquefying non-spore formers *Pseudomonas fluorescens* (Flügge) Migrila and *Ps. caudatus*, (Wright) Conn (2) are of primary importance in ammonification in manured soils. The soil used throughout the series of experiments was Dunkirk silty clay loam.

Nearly all the plate counts were checked by direct microscopic examination of soil according to the CONN method (3). In the first place it is clearly demonstrated that the non spore organisms predominate in freshly manured soil to the rate of 99 % of entire flora; this supports the theory upheld by CONN (3).

Secondly, the growth of *Ps. fluorescens* and *Ps. caudatus* compared with the growth of the spore forming *Bacillus cereus*, in sterilised manure soils, gave results indicating that the non spore forming organisms rapidly gain ascendancy over *B. cereus*. The vegetative cells of the latter soon sporulate and remain in resting condition.

All three of these organisms are vigorous ammonifiers when tested in pure culture.

Tables show the relative numbers of organisms, present in the soil, before and after adding manure and the results of inoculating with the 3 organisms separately and in a mixture

Section II gives a detailed description of the characteristics of the non-spore forming Bacteria and discusses the probable relationships of these organisms to others. *Ps. caudatus* is now believed to be identical with *Bacillus caudatus*, Wright 1895, referred to by CONN as the " orange liquefying type " (2).

253 - **Effect of Liming on Acidity in Plant Juices.** — See Nos. 260 and 261 of this *Review*.

254 - **The Duty of Water in Cache Valley, Utah.** — HARRIS F. S., in *Utah Agricultural College Experiment Station Bulletin* No. 173, pp. 2-16 figs. 9, Tables 5. Logan, Utah, March 1920.

A report of experiments on the relation of the amount of irrigation water applied to the yield of crops, including sugar-beets, potatoes, alfalfa, maize, wheat and oats raised on a deep medium soil. The results include a total of 991 tests extending over a period of 17 years. The figures refer to water that actually soaked into the land. In ordinary practice it would be necessary to make allowances for ditch and run-off losses The results can be said to hold good only for soils of the same general type as those on which the experiments were conducted, although they should be useful in estimating the water requirements on other types of soils.

---

(1) See *R.* 1918, No. 1334. — (2) See *New York Agricultural Experiment Station, Technical Bulletin*, No. 67. — (3) See *R.* 1918, No. 259. (*Ed.*)

For sugar beets from 15 to 30 inches of water gave the best results. The yield of potatoes was augmented with increased irrigation up to 32 ½ inches, but dropped off rapidly when applications above 60 inches were made. Alfalfa was able to use more water advantageously than any of the other crops. The highest yield was secured with 50 acre inches, although nearly as high with 25 inches. Alfalfa was found to be much less sensitive to over-irrigation than potatoes and sugar beets. From 15 to 22 acre inches of water gave the best results with maize. With wheat, 15 inches of water gave almost as high a yield as any treatment and yet the yield kept up fairly well with the very high irrigations Where no irrigation water was applied, the yields were fairly satisfactory. Oats appeared more sensitive to moisture than wheat. The yields did not differ noticeably for quantities of water between 15 and 45 inches.

The proper diversification of crops made the most efficient use of irrigation water possible.

The proper amount to use must be based on a great variety of physical and economic factors that vary with each set of conditions.

255 - **Electroculture.** — I. MacCrecy R. D., The Theory of Electro Culture. *Scientific American*, Vol. CXX, No. 20, p. 530. New York, 1919. — II Electroculture at Chester. *The Electrical Times*, Vol. LV, p. 205. London, 1919. — III. Blackburn, A. E., Electrochemical Treatment of Seed Grain (Paper read before the British Association for the Advancement of Science, and Discussion), *The Electrical Review*, Vol. LXXXV, pp. 377-379. Id. (1)

I. — When direct current is driven through an electrolyte the negative ions move to the positive electrode and the positively charged ions more to the negative electrode. When alternating current is used this is not the case; the ions move rapidly first in one direction towards one electrode, then in the opposite direction towards the other. They are as it were in a state of intense vibration of an oscillating nature, caused by and in unison with the waves of the alternating current. What then happens if we discharge high frequency electricity through an acre of soil to metallically coated seed, from electrodes (parallel to each other), embedded in the earth?

The earth is in this case the electrolyte, in which, by the action of water, there have been gaseous ions set free. When the electricity is applied, these ions set up an active bombardment on the seeds and tiny roots of the plantlet and since the seeds and roots are porous it must be evident from a mechanical standpoint that some absorption, by the plant, of the gaseous ions takes place. After being absorbed by the plant roots these ions are still subject to the influence of the high frequency electricity which during application, will set up vibrations within the cells of the plant. Such an action will mechanically enlarge the cells in the tissues of the plant and allow it to grow more freely.

The discharge of high frequency electricity through soil is also equivalent to aeration since it causes air to be drawn into the soil with it. This is in a great measure the principal benefit derived from cultivation and is, therefore, an important factor in agriculture because of its stimulation of bacterial action. Moreover the discharge of high frequency electricity through the air combines with the moisture in the soil to produce nitric acid, which contains nitrogen in a form readily available as plant food

---

(1) See *R.*, 1919, Nos. 686 and 720. *(Ed.)*

On the other hand the electronic collisions of the ions with alkalies in the earth produce nitrites. The earth in a sense becomes a storage of nitrogen that must be changed by the soil bacteria before it becomes available as plant food. This makes work for the soil-building bacteria. In 1909, Prof. G. E. STONE of the Massachusetts State Agricultural College, proved in a series of tests that by discharging each day a few sparks of static electricity through soil containing bacteria these organisms in 17 days increased 600 per cent. There is another influence of electricity on the bacteria which might be termed bacterial stimulation. Bacteria are sluggish micro-organisms and the galvanic action of the current on their bodies increases their activity.

With the above proven facts in mind, it is not at all surprising that increases in production have been reported where electricity has been properly applied to promote the growth of vegetation.

II — A short note is given of the results obtained from electroculture with electric discharge at Chester. The outstanding fact is that the four varieties of potato that were tried gave decreases. On the other hand, peas, broad beans, French beans, and beetroot gave increased yields of 27,6,8 and 88 per cent. respectively, compared with the control. It is suggested that the bad results were due to the abnormal rainfall when the growth was nearing maturity.

III — Experiments on the electrochemical treatment of seeds are referred to (1) in which the seeds, 10 or 20 sacks, were placed in tanks provided with iron electrodes at both ends; the electrolyte was a solution of sodium nitrate or some other fertiliser. Particularly with cereals (wheat, barley, oats) the yields of both grain and straw are increased. Some 500 farmers have taken up the treatment of the seeds, which is followed by a very careful drying in a kiln and applied a month or two before sowing.

In the discussion A. E. BAINES suggested that a dry seed buried in the soil would become charged in the earth-atmosphere field after the manner of a Leyden jar, when electrodes were applied above and below the seed the current would favour growth of the roots or of the stem according to its direction. BRENCHLEY said that the Rothamsted experiments gave doubtful results; ROSS THOMPSON drew attention to the importance of the nature of the soil; G. H. GARRAD thought that the beneficial effect was not lasting; whilst DUNN and ANDERSON recommended the treatment.

256 - **The Lime Factor in Permanent Soil Improvement. — I. Rotations without Legumes. — II. Rotations with Legumes.** — LIPMAN, J. G. and BLAIR, A W., in *Soil Science*, Vol IX, No. 2, pp. 83-114, tables 17, bibliogr of 8 works. Baltimore M. D, Feb. 1920.

A report of work covering a period of 10 years including the study of the sources of nitrogen, the proper amount to apply, the influence of nitrogen on the yield and composition of the crop, denitrification and other nitrogen losses. On account of the important bearing which the reaction of the soil has on the nitrogen problem, the plan was made to include the use of lime in the carbonate form.

---

(1) See *R.* January, 1921, No. 21. (*Ed.*)

I — The soil on which the experiments were conducted contained originally 0.11% nitrogen and 1.22% of total carbon, and no lime had been applied within recent years. The lime treatment consisted of finely ground limestone or oyster shells at the rate of 1 ton per acre just before planting the maize in 1908, and 2 tons per acre again preceding the maize in 1913, the liming thus taking place at intervals of 5 years. A careful record was kept of the amount of nitrogen applied in the form of manure and fertiliser, and likewise of the amount removed by the crops. The 5 year rotation practised was maize, oats, wheat and 2 years of timothy No legume crops were introduced. Twenty plots with different nitrogen treatment were thus limed, and 20 similar plots with parallel nitrogen treatment were left without lime. The total yield of dry matter and of nitrogen for the 10 year period were essentially the same for the 2 sections.

Analysis of the soil made soon after the work was started and again at the end of each 5 year period, showed that there was a loss of nitrogen from both the limed and unlimed sections. However, the loss from the limed section was distinctly more marked.

Results appear to indicate that the practice of using lime on light to medium heavy soils, when leguminous crops are not grown in the rotation, may be questionable. Under such conditions it is quite possible, according to the authors, that a slightly acid reaction may be desirable to prevent the too rapid oxidation of organic matter. On acid peat soils, and poorly drained heavy clay soils, where there is a large amount of oxidisable organic matter, or where oxidation proceeds very slowly, lime may however be used in connection with the growing of non-legume crops to excellent advantage.

II. — An attempt is made to show the influence of lime in 4 different rotation systems, all of which include some legume crops, either as one of the main crops, or as a green manure between the main crops. Two 5 year periods for each rotation were completed. Acid phosphate 300-400 lb., and muriate of potash 100 lb. per acre were applied and light applications of commercial nitrogenous fertilisers were also made. No farmyard manure was used.

During the 10 years the limed plots, with only slight exceptions yielded distinctly larger crops and more nitrogen than the unlimed plots. In most cases, the yields were larger with the 2000 and 4000 lb. applications, than with the 1000 lb. application. There appeared to be a slight difference in favour of the magnesium lime-stone, in preference to the calcium limestone.

The use of lime thus resulted in a gain in both quantity and quality of the crops produced. Analysis of the soil showed that in a number of cases, there was a higher nitrogen content for limed than for unlimed plots ; in other cases, the two were about on a level as to nitrogen content and in a few cases, there was apparently a development of nitrogen in the limed plots.

Compared with the results of the former experiments the authors suggest that in using lime, emphasis should be laid on its power to make conditions favourable for the organisms associated with leguminous crops rather than on its power simply to neutralise soil acids. Its value is more indirect than direct.

257 - **Effect of Manure Sulphur Composts upon the Availability of the Potassium of Greensand** (1). — McCall, A. G. and Smith, A. M., in *Journal of Agricultural Research*, Vol. XIX, No. 6, pp. 239-256, Tables 9, bibliogr. of 13 works. Washington D. C., June 15, 1920.

Report of the results obtained by the Department of Soil Investigations, Maryland Agricultural Experiment Station in connection with experiments on the effect of composting greensand, with sulphur, manure and other materials with a view to making available the potassium contained in the greensand. The samples were taken at intervals, and extracted with distilled water, analysing the water extracts for acidity, sulphate and potassium content.

Two series of composts were investigated, one containing 5.88 % of potassium and the other 1.42 %, in studying the effect of sulphofication upon the solubility of the potassium.

The outstanding results may be summarised as follows:

The composts consisting of greensand, farmyard manure and soil in different proportions showed that an appreciable amount of the potassium of the greensand was made water soluble through sulphofication The composts containing the largest proportion of manure, developed the highest degree of acidity, oxidised the greatest amount of sulphur, and produced the largest quantity of water-soluble potassium. The quantities were smaller in the case of composts in which soil was substituted for a part of the manure. When all the manure was replaced by soil, the rate of sulphofication was so slow that at the end of 23 weeks, only a very small amount of acidity had developed and very little potassium had been made soluble.

The addition of small amounts of ferrous and aluminium sulphates failed to stimulate sulphofication. The addition of 10 gm. of calcium carbonate to the sulphur manure soil compost, had a marked stimulating effect during the early part of the period, but failed to increase the acidity, soluble sulphates, or potassium above the maximum reached by the corresponding compost in which no calcium carbonate was used (2).

With the increase in acidity and the accumulation of sulphur trioxide there was a corresponding increase in the amount of potassium in the water extract. The larger amounts of acidity and soluble sulphate appeared to break down the greensand more rapidly than small quantities. The larger percentage of the total potassium present was liberated in the compost containing the low-potassium greensand.

---

(1) See *R.* Jan. 1919, No. 24, and *R.* June 1919, Nos 693 and 694

(2) See *R.* Jan. 1920, No. 18 (*Ed.*)

In the composts containing manure, the total amounts of potassium recovered in the water extracts varied from 9.1 % to a maximum of 41.3 % of the total initial amount present.

Results indicate that the composting of greensand, or of soil rich in potassium, with sulphur and manure, may prove to be a practical and efficient method for obtaining available potassium from comparatively insoluble materials.

258 - **A Survey of the Fertiliser Industry.** — GOLDENWEISER, E. A. (Statistician, Prepared under the Direction of MEIN W. W., Assistant to the Secretary in Charge of Fertiliser Control), in *United States Department of Agriculture Bulletin* Nov. 798, pp. 1-29, fig. 1, map 1, tables XII, bibliogr. of Govt. Publications. Washington, D. C., Oct. 20, 1919.

The U. S. Fertiliser Control, created under authority of the food control act as a war emergency measure in the Department of Agriculture, soon after its establishment, undertook a survey of the Fertilizer industry in order to determine the material used, the products, and the stocks of ingredients and of mixed goods on hand. In view of a serious shortage of several of the materials that enter into the manufacture of fertilisers, it was deemed important to ascertain what the requirements of the industry were, in order to stimulate production of the scarce ingredients, and, if it became necessary, to apportion the available supply of scarce materials on an equitable basis. A series of questionnaires was sent out by the office of Fertilizer Control. The information collected is for the calendar years 1917 and 1918. No comparison with pre-war years can be made, for lack of data, but a future survey of the industry in years after war activities have ceased will afford interesting comparison

Table I shows the amount of materials of different kinds used in the manufacture of mixed fertilisers during the year 1917 and 1918.

The figures for 1918 are not altogether comparable with those for 1917, as 55 companies included in the tabulation for 1917 and for the first six months of 1918 failed to make reports for the last six months of 1918. In the case of acid phosphate an estimate has been made to cover the companies for which reports were not received for July to December, 1918.

Table II shows the quantity of materials used in the manufacture of acid phosphate during 1917 and the first 6 months of 1918.

The production of phosphate rock is conducted by a number of fertiliser companies and by other producers, mostly in Florida. Many of the great fertiliser companies are interested in the phosphate fields and are producing their own rock.

Table III shows the sources of nitroger (ammoniac) used in mixed fertilisers. The principal source of nitrogen is sodium nitrate, the second

	100.0	100.0

The total amount of nitrogen calculated as ammonia used during 1917 was more than 18 600 000 units of 20 lb., and the total amount used during 1918 exceeded 15 000 000 units. Base goods is a name by which the companies call preliminary mixtures, that are stored in large bins against the time when orders need to be filled and the base goods are mixed with the other ingredients to obtain a desired grade of goods.

A special enquiry was made for tankage and table IV shows the total quantity of tankage and allied materials produced in 1917 and 1918 and marketed in 1918.

TABLE IV.

In connection with cottonseed meal an enquiry was made from all the mills that manufacture cottonseed oil and meal as to the amount produced during the fiscal year July 1, 1917, to June 3, 1918, and the amount disposed of for different purposes and different ways. In the aggregate, two thirds of the cottonseed meal was used as feed and one-third as fertiliser, with however, considerable variation in this respect between the different States (See Table V.)

In pre-war years the United States consumed yearly about 250 000 tons of potash, practically all of which was imported from Germany. When the German supply was cut off in 1914, the United States turned its attention to domestic production, which has increased to 53 000 tons in 1918, about one-fifth of the annual pre-war consumption. Some crops probably have suffered during this period from a lack of potash, but the main needs were supplied. The price of potash rose from between 75 cents and $1 a unit to between $4 and $5 a unit, and with this great increase in price the domestic manufacturers entered the field of production. Whether the American potash industry will be able to survive under normal conditions is an open question.

Finally table VI shows the production of mixed fertilizer andmaterials sold as such during 1917 and 1918.

TABLE VI.

2 000 lb. tons.

Kind of material	1917	1918
	tons.	
Mixed fertilizer produced	4 442 528	4 957 799
Materials sold as such:		
Acid phosphate	2 097 232	2 024 574
Phosphate rock	393	542
Bones: Raw bones	10 023	7 532
Steamed bones	698	3 249
Raw bone meal	11 379	15 707
Steamed bone meal	683	1 336
Tankage	8 114	37 827
Blood	3 126	2 304
Fish scrap	1 749	1 889
Cottonseed meal	6 682	7 987
Natural guano	1 152	6 266
Nitrate of soda	7 241	11 334
Ammonium sulphate	531	2 334
Cyanamid	117	4

Of the 2 000 000 tons of acid phosphate reported sold as such, a considerable quantity was sold to dry mixers who used it in preparing the final product. The quantity of acid phosphate used by dry mixers in 1917 was 494 261 tons, leaving about 1 50 0000 tons of acid phosphate sold for direct application to the soil. Certain quantities of bone, tankage, blood, fish scrap, and cottonseed meal were sold in their original state; also some nitrate of soda, but beginning with July, 1918, practically no nitrate of soda was sold as such.

259 - **Variation in Sexuality, Dioecism and Sexual Dimorphism of *Pinus montana* and *P. sylvestris*.** — GUINIER, P., in the *Comptes rendus des Séances de la Société de Biologie*, Vol. LXXXIV, No. 2, pp. 94-96. Paris, Jan. 15, 1921.

Under normal conditions, the various species of the genus *Pinus* are monoecious, both male and female inflorescences being evident on the new shoots even at the beginning of their growth. The fruiting branches or catkins, develop in the axil of the involucre inserted at the base of the shoots and are short, modified branches generally, and invariably with *Pinus sylvestris* L. and *P. montana* Mill., the fertilised female inflorescences are borne only at the apex of the shoots, on a level with buds arranged in a false whorl, which, the following season, will produce lateral branches, whilst these fertile branches, in the course of natural growth, will be transformed into cones. The female branches have therefore the morphological value of long branches that develop sooner.

The distribution of the two types of inflorescences is clearly relative to the vegetative vigour of the branches bearing them. The catkins, always much the most numerous, are distributed indiscriminately over the tree, existing, however, only on the less vigorous parts, such as at the base of the branches, and generally below the apex. The less common female fruiting branches are found only at the apex of the vigorous branches, especially on the highest branches. Usually, the spurs bearing female inflorescence also possess catkins at the base; however, some shoots bear only a male inflorescence.

In *P. montana* and also with *P. sylvestris* a tendency has been observed towards dioecism, or, more accurately, a sort of polyoecism, which is evinced by the existence of a number of male plants by the side of monoecious plants. NORDLINGER has observed the fairly frequent dioecism associated with *P. montana* and, more recently, SCHRÖTER has remarked on the same fact in Switzerland.

Similar observations have been made regarding the northern type *P. sylvestris* var. *lapponica* by Scandinadian workers. The author has observed that, in the vast forest of *P. montana* sub sp. *uncinata* Ramond in the Capcir region in the Montlouis district (E. Pyrenees), this Pyrenean type presents the same peculiarity and amongst a big group of trees comparatively rich in female inflorescences, certain trees bear males only.

Dioecism, in the case of pines, is accompanied by a certain sexual dimorphism. On a normal monoecious tree., the branches terminating in male inflorescences present distinct morphological differences. On the less vigorous branches arising each year from a minor quantity of male inflorescences, the catkins are distributed over the major part of the new shoots, and only a small area is left at the apex for the short leaf-bearing twigs. After the catkins have fallen, a long bare strip is left at the base of each new shoot, whilst the leaves form a collar at the top of the shoots. Quite different is the appearance of the vigorous branches terminated by female inflorescences. These branches are of considerable length and the shoots are almost entirely covered with leaves. At the base of each shoot, there is a short defoliated area which may be attributed either to the fall of the catkins or to the normal absence of twigs at the axil of the lowest leaf scales. As regards the males, all the branches belong to the first type described: some botanists have compared them to the stems of *Equisetum* on account of the apparently whorled arrangement of the leaves. BEISSNER with reference to male individuals of *P. montana* and BENVALL to males of *P. sylvestris* var. *lapponica* have established a new form, namely *equisetiformis*. BEISSNER even considered that it constituted a genuine variety; SCHRÖTER and VON TUBEUF have established the real cause of the morphological peculiarity observed.

The author has also observed that certain peculiarities are noticeable amongst a group of *P. montana* subsp. *uncinata* in the Pyreneees. The Pyrenean type is characterised, amongst other things, by its slender habit, a compact conical crown, with rigid branches, curved from the base upwards. On the other hand the males have wider spread branches, more or less intertwined, less abundant foliage and a more irregular and spreading crown.

SCHRÖTER had previously drawn attention to the fact that the males possessed a more open branching system. This difference can only be attributed to less vitality and to the slower growth of the male branches, as a whole.

Occasional cases of dioecism with *P. montana* are considered by the authors to be due to individual peculiarities. The phenomenon, is apparently influenced by physiological conditions which cause variations in individual vitality particularly with reference to age and to vegetative conditions. RENVALL has shown that with *P. sylvestris* var. *lapponica*, although the young trees always possess female inflorescences, the other trees tend to produce an ever increasing proportion of males and,consequently, no cones, and that trees growing on poor soil behave similarly. In the Eastern Pyrenees, the males of *P. montana* subsp. *uncinata* in question (all of a fairly advanced age) were growing on soil of mediocre fertility; the foresters have however, observed that, in that district, the older trees produce but little seed.

Sexuality in *P. montana* and *P. sylvestris*, depends therefore on the development of the vegetative apparatus; the production of female inflorescences necessitates a certain vitality of the shoots, whilst with retarded growth only males are formed. The variations in sexuality can thus be explained, and also to a certain extent the tendency to dioecism. The morphological peculiarities of both male or female spurs, which lead in the most accentuated cases to sexual dimorphism for male individuals are only the consequence of these facts.

260 - **Studies on the Reaction of Plant Juices.** — HAAS, A. R C. (Departments of Agricultural Bacteriology and Soils, University of Wisconsin), in *Soil Science*, Vol. IX, No. 5. pp. 341-368, pl. 1. figs. 11, bibliogr. of 18 works. Baltimore, M. D., May 1920.

The investigations made by the author deal with the actual and total acidities (1) and the total alkalinity of the juices of a number of plants of agricultural importance, together with a study of the influence of liming the soil upon these acidities. The effect of age, lack of chlorophyll and changes in illumination upon the actual and total acidities of plant juice are also considered. These determinations were made by the use of the hydrogen electrode. The plants employed included clover, serradella, garden beans, barley, oats, maize, alfalfa, field peas, lupin, mustard, timothy, wheat and buckwheat.

The most noticeable difference in the actual acidity of the juice from plant on limed and unlimed soil was with the buckwheat seedlings., *i. e.*, pH = 5.48 to 5.97 respectively (p = index of acidity in a solution), whereas in the mature conditions a reaction of pH = 4.82 was reached. Apparently the degree of maturity of a plant seems to be an important factor in the degree of actual acidity attained. The general results with all the plants used in this experiment indicate that the actual reaction of the juice of many agricultural crops is distinctly acid.

---

(1) Actual acidity indicates amount of dissociated acid Total acidity includes both dissociated and undissociated acids. (*Author's Note*)

The alkali reserve (1) of the roots of medium red clover and of sweet clover, according to the determinations made, is less than that of the leaves, even though the actual acidity of the roots is greater than that of the leaves. The results from the two species may therefore serve as a rough comparison of the relative amounts of carbonates and bicarbonates in the juice of the 2 species. The unique case of a single plant having juice with a markedly alkaline actual reaction and a steep gradient in actual reaction is reported.

The observations made up to the present time with regard to the total acidity, appear to show that this tends to fluctuate in the same direction as the actual acidity, with exceptions. The juice of the younger portions of a plant usually show a lower actual acidity than the older portions.

A preliminary experiment was made with maize seedlings, and the total acidity of the juice of seedlings lacking chlorophyll was less than that of tops containing chlorophyll until about pH = 8.6 was passed, after which conditions were reversed.

The effect of light on the reaction of the juices, showed that both actual and total acidity decreased with a reduction of normal illumination.

The author considers that these results support the suggestion made by TRUOG that the main specific harmful influence of soil acidity on certain plants is due to its influence in preventing the plants from securing sufficiently rapidly the bases that are needed to neutralise and precipitate acids within the plant.

261 – **Acidity of Buried Herbaceous Plants and the Lime Soil.**— MASONI, G (Istituto di Chimica agraria della R. Università di Pisa), in *Le Stazioni sperimentali agrarie italiane*, Vol. LIII, Part 12, pp. 421-437. Modena, 1920.

The author observed in 1914, that on mixing the sap of young maize plants with calcareous soil and an excess of calcium carbonate, the sap retained its acid reaction even after 4 or 5 days and only acquired a neutral and then alkaline reaction after putrefaction. On account of the interest of this fact in relation to the burying of green herbage and as regards the investigation of the acids in fresh and in decomposing vegetable matter, the author has taken up this study with the aid of a series of experiments, which have led to the following conclusions :

Acid saps of young herbaceous plants (maize, lucerne, and beet) when placed in contact with calcareous soil and even with pure calcium carbonate (precipitated), the carbonates being greatly in excess of the acids, retained their acid reaction for several days. This also occurs with saps tested immediately after extraction as well as with saps in which acid fermentation had taken place.

---

(1) Alkali reserve equals the change in the actual reaction of the juice upon the addition of acid. (*Author's Note*).

Total or partial sterilisation retarded the neutralisation of the free acids in contact with the lime which coincides very often with the putrefaction of the saps.

When fresh or fermented saps were heated to boiling point with calcareous soils or pure calcium carbonate a distinct acidity was maintained when soils were used, and this acidity persisted for several days. With pure calcium carbonate there was an appreciable decrease in acidity, but it was not completely neutralised, except in the case of fresh beet sap.

Solutions of numerous acids and organic acid salts of different concentrations and presenting degrees of acidity and corresponding approximately to the acidity found in the saps (expressed in terms of normal alkali), were quickly neutralised on contact with the calcareous soils and with pure calcium carbonate, either in the cold or after boiling.

On the contrary, solutions of monopotassium phosphate and monocalcium phosphate in concentrations corresponding to those precipitated, retained, when in contact with the same soils, an acid reaction for several days either in the cold or after boiling in contact with pure calcium carbonate; in the cold, they were neutralised more quickly, and very rapidly after boiling.

The proteins, starches and sugars present in the sap, do not impede the reaction between the acids and the lime.

The lime in the soil does not neutralise either the congenital acidity of the plants or their fermentation products. The author estimates that the permanence of the acidity of vegetable saps is due to the fact that the acid phosphates of alkali metals and alkali earths resist, under similar conditions, saturation by the lime in the soil, and also because there is less monopotassium phosphate in the sap.

As regards green manure, the lime in the soil has but a secondary action in neutralising the acidity of the buried plants, that is to say, only to such an extent as to favour putrefaction with the resulting formation of basic substances.

In the first phase of the green manure, the acidity of the sap, even in the presence of lime, is increased by fermentation, especially of the sugars. It is known that green manure aids the dissolution of the mineral matter in the earth ; these experiments show that this dissolution is not due to the acidity of the plants.

262 – **Research on the Diffusion of Sulphocyanic Acid in Plants.** — DEZANI, S. (Laboratorio di materia medica e Jatiochimica, Turin), in *Le Stazioni sperimentali agrarie italiane*, Vol LIII, Part 1, pp 438-440, bibliography of 6 works Modena, 1920.

The results of the author's researches are summarised in the appended table. The — sign indicates that the classic reactions for sulphocyanic acid (with chloride of iron, copper sulphate, calomel, hydrogen peroxide, and chloride of iron), gave negative results. A single + sign indicates that the reaction was slightly positive, and + + intensely positive.

The table shows that, of the plants examined, the Cruciferae were the only ones which contained sulphocyanic acid, and that this compound is widespread in this family.

The author has found that hay contains this acid in proportion to the quantity of Cruciferae it holds. It is probable that this acid is a direct product of the cellular metabolism of the Cruciferae and is not produced through the decomposition of the esters of isosulphocyanic acid, nor is it derived from enzyme action which take place after the death of the plant.

263 – **Some Proteins from the Georgia Velvet Bean *Stizolobium Deeringianum* and the Mungo Bean (*Phaseolus aureus* Roxburgh).** — JOHNS, C. O. and WATERMAN, H. C., in *The Journal of Biological Chemistry*, Vol. XLII, No. 1, pp. 59-69, Tables X; Vol. XLIV, No 2, pp. 303-317, Tables IX. Baltimore, May and Nov. 1920.

I. — The Georgia velvet bean is a sport of the Florida velvet bean, *Stizolobium Deeringianium*, from which it differs principally in having the shortest season of all the cultivated *Stizolobia*, and so can be successfully grown in the extreme northern part of the cotton belt. An examination of the closely related Chinese velvet bean, *Stizolobium niveum* has already been made (1).

The bean in question was found by the authors to contain 23.6 % of protein (N × 6.25), and 3 % sodium chloride solutions extracted a maximum of about 15 % protein from the finely ground seed. A yield of 13 % of mixed proteins is stated to be obtainable by coagulation from the slightly acidified extract at the boiling temperature. By the fractional precipitation of the extract with ammonium sulphate, however, and by subsequent purification of the fractions, two globulins, designated α- and β-globulins, were separated, in yields of about 3 and 1.25 %, respectively. The former contained 90 % of sulphur and coagulated at 70-78° C., and the latter 45 % of sulphur with coagulation at 90-100° C. An albumin was found in extracts freed from globulin by repeated dialysis. The latter protein coagulated in yields of about 75 % by the prolonged heating of its slightly acidified solution at 65° C. Analysis of the three proteins obtained by this method, showed marked differences in the nitrogen and sulphur content, and in the distribution of nitrogen as determined by VAN SLYKE'S method (*Journal of Biological Chemistry*, Vol. x, 1911-12, No. 15).

---

(1) See *R.* Sept. 1918, No. 965. (*Ed.*)

Qualitative examination indicated that the β-globulin contained no tryptophane, an observation of particular interest in view of the fact that this amino-acid had been found to be present in all seed globulins heretofore tested. The α-globulin and the albumin from the Georgia velvet bean both contain tryptophane.

II. — The mungo bean or green gram is cultivated throughout the southern half of Asia, especially in India; in the Malay Islands, and quite generally throughout the eastern portion of Africa, and with a certain degree of success also in mid and southern United States.

The protein content was found to be about 21.74 % (N × 6.25). A series of experiments made with aqueous solutions of sodium chloride indicated 5 % as the most effective concentration of this salt for extraction purposes. From the finely ground seed, 20 volumes of 5 % sodium chloride solution dissolved about 19 % of protein, calculated on the dry weight of the meal used, or 87.5 % of the total protein. The coagulation points in the above mentioned extract and their precipitation limits with ammonium sulphate were next determined. A very low coagulation point (about 40°C), together with two others at higher temperatures indicated an albumin and two globulin fractions, the first precipitated at from 0.15 to 0.20 of saturation and the second at 0 65. The procedure of the fractionation of the globulins was essentially the same as that used in isolating the globulins of the Georgia velvet bean. The yields were 0.35 and 3.75 for α- and β- respectively, computed on the basis of the dry material extracted. Traces of albumin were also obtained from extracts from which all the globulin had been precipitated by prolonged and repeated dialysis. The albumin remained in solution during the dialysis, and was separated by slightly acidifying and coagulating at 45° C. The yield of the albumin was from 0.02 to 0.05 % of the weight of the bean meal.

Analysis showed marked differences in the nitrogen and elementary composition of the 3 proteins. The globulins were still further distinguished from each other by marked differences in their percentage of the basic amino-acids, determined by the VAN SLYKE method. The β-globulin contained so little cystine that, remaining undecomposed after hydrolysis it escaped precipitation by phosphotungstic acid and the said method was therefore impracticable in this case.

264 - **Protein Investigations with the Coconut — I. Some Amino-Acids from the Globulin as Determined by the Butyl Alcohol Extraction Method of** DAKIN. — **II. Hydrolysis of the Globulin of *Cocos Nucifera*** — JOHNS, C. O., and JONES, D. B. (Bureau of Chemistry. United States Department of Agriculture, Washington), in *The Journal of Biological Chemistry*, Vol. XLIV, No 2, pp. 283-301, Bibliogr. of 12 works Baltimore, May and Nov. 1920.

I. — A determination of the amino-acids which remain in the aqueous solution of the hydrolysis products of coconut globulin after it has been subjected to extraction with normal butyl alcohol according to the DAKIN method (*The Biochemical Journal*, 1918, Vol. XII, p. 290). By this method practically the whole of the di-basic acids and the diamino-acids are contained in the aqueous solution. Glycine and serine are also only extracted with difficulty. The coconut globulin used for this hydrolysis was prepared as described in the JOHNS, FINKS and GERSDORFF experiments (1) Attention was confined chiefly to the amino-acids remaining in the aqueous solution after the extraction.

The following values were found: glutaminic acid, 19.07 %, aspartic acid, 5.12 %, alanine, 2.76 %, and serine 1.76 %. No hydroxyglutaminic acid or glycine could be detected. From the amino-acids extracted by the butyl alcohols, 5.4 % proline, and 0.64 % of leucylvaline anhydride were isolated.

II. — A complete determination of the degradation products was made according to methods not involving extraction with butyl alcohol. The authors were able to give percentages of those amino-acids which had not been determined in the previous hydrolysis, and also to furnish supplementary data for comparison with those already obtained.

78.15 % of the hydrolysis products of the protein used, was identified and determined. The following gives the amino-acid content in coconut globulin to the highest value obtained % :—

Glycine-trace — alanine 4.11 — valine 3.57 — leucine 5.96, — proline 5.54 — phenylaline 5.54 — aspartic acid 2.05 — glutaminic acid 19 07 — hydroxyglutaminic acid 0.00 — serine 1.76 — tyrosine 3.18 — cystine 1.44 — arginine 15.92 — histidine 2.42 — lysine 5.80 — tryptophane present — leucylvaline anhydride 0.64 — ammonia 1.57.

265 - **Action of Chloropicrin on the Germination Power of Seed** (2). — MIÈGE, E., in the *Comptes rendus de l'Académie des Sciences*, Vol. CLXXII, No. 3, pp. 170-173 Paris, Jan. 17, 1921.

Various workers have shown that chloropicrin is a powerful insecticide which is effective for the destruction of certain parasites. The action of chloropicrin on the germination power and the cultural value of seeds, however, remained to be determined.

---

(1) See *R.* April 1919, No. 439. (*Ed.*)

(2) See *R*, July-Sept, 1919, Nos 1049-1050; *R.* Jan., 1920, Nos. 6 and 148; *R.*, Feb. 1920, No. 274; *R.* Mar., 1920, Nos. 374 and 378; *R*, May, 1920, No 595; *R.*, June, 1920, No. 705

In a previous experiment on a large scale several quintals of different infested seeds (pea, bean, wheat, etc.) were treated, either by watering the closed sacks, in the way indicated by M. G. BERTRAND, or by placing the chloropicrin in vessels placed close to them. With a dose of 20 cc per cubic metre of space, or per sack of about 80 kg. the pea-weevil (*Bruchus pisi*), bean-weevil (*Br. obtectus*) and the grain-weevil (*Calandra granaria*) were, in both cases, radically destroyed within 24 hours without any apparent harm to the germination power. The wheat alucide (*Sitotroga cerealella*) was also completely destroyed under similar conditions.

In a second series of experiments in the laboratory, samples of seeds of various cultivated plants were placed in dishes under a bell-jar and treated for varying periods with chloropicrin in doses varying from 15 to 50 cc. per cub. metre. Afterwards the seeds were removed and put to germinate under filter paper, in the open air without artificial heat, and compared with untreated controls The following tables give the results obtained: —

TABLE I. — *Germination power after treatment with* 15 *cc. of chloropicrin per cubic metre.*

Duration of treatment	Wheat	Rice	Hemp	Flax	Lentils	Fenugreek	Bersim
Control	100	80	69	100	100	100	100
6 hours	93	84	50	100	100	100	100
12 »	82	79	61	100	100	100	100
24 »	70	79	58	100	100	100	100
	66	60	54	100	100	100	100
72	69	39	65	100	100	100	100
96	71	38	64	100	100	100	100

TABLE II. — *Germination power after treatment with* 50 *cc. of chloropicrin per cub. metre.*

Duration of treatement	Wheat	Beet	Flax	Lentils	Fenugreek	Bersim
Control	100	72	100	100	100	100
6 hours.	34	61	95	99	100	100
12 »	36	65	96	100	100	100
24 »	32	58	91	100	100	100

The results show that the destruction of insects parasitic on seeds (wheat and bean weevils, alucides, etc.) is assured by the use of chloropicrin, acting for 24 hours in doses of 15 to 20 cc. per cubic metre. Longer periods of contact and larger doses do not appear to be any more effective.

TABLE III. — *Germination power of wheat treated with 20 cc. of chloropicin per cubic metre.*

Appearance of first sprout		Reference	6 hrs.	12 hrs.	24 hrs.	48 hrs.	72 hrs.	96 hrs.
		3rd day	2nd day	3rd day	3rd day	3rd day	4th day	5th day
Number of germinations after	4 days	54	65	40	53	25	7	0
	6 »	73	77	69	58	49	40	24
	8 »	85	84	76	65	58	54	50
	10 »	94	88	80	71	62	57	62

The action of the chloropicrin on the seeds varies with their nature, the dose given, and the duration of treatment. Certain seeds of legumes, flax, etc. are not affected by it, but on others, such as hemp, beets, etc. and, in particular, cereals it affects the germination energy and power. This unfavourable influence usually increases, with the quantity used and the time of contact.

Under the conditions required for disinfection the germination power of wheat is decreased by 30 %, a percentage which increases with stronger doses. On the other hand leguminous seeds are absolutely immune.

266 - **The Assimilation of Carbon Dioxide by Green Plants.** — MAZÉ, P., in I. *Comptes rendus de l'Académie des Sciences*, Vol. CLXXI, No. 26, pp 1391-1393. Paris, Dec. 27, 1920. — II. *Ibid.*, Vol. CLXXII, No. 3, pp. 173-175. Jan. 17, 1921.

I. — Green leaves gathered under sunshine yield substances with an aldehyde action when distilled. The formation of these substances has been attributed to the chlorophyll and some authors, thinking that they had succeeded in identifying the formaldehyde among them, have seen in their results a confirmation of the hypothesis of BAYER and BERTHELOT concerning the synthesis of sugars by green leaves.

The author has tried to give an experimental basis to this hypothesis by making maize plants cultivated in an aseptic medium, absorb solutions of mineral nutrients containing 1-2 gm. of methyl alcohol per litre. But this method has not yielded conclusions favourable to this hypothesis.

He has extended his investigations moreover to the chemical action that takes place in green leaves. Gathered under various atmospheric conditions, the green leaves were at once distilled, without the addition of water, under a reduced pressure at 60° C. The analysis were made on oak, horse-chestnut, sycamore, lime, poplar, clove, elder, spindle, privet, lilac, rose, vine, white clover, lucerne, pea, bean, maize, ray-grass, beet, Jerusalem artichoke, dahlia, dandelion, chrysanthemum, lettuce, carrot, celery, cabbage, potato and night-shade. They did not indicate the least trace of formaldehyde, but nearly all gave ethyl alcohol, acetic aldehyde and nitrous acid. Bean and maize leaves gave acetylmethylcarbinol when the weather was very fine, the elder leaves gave free hydrocyanic acid and glycolic aldehyde, and the poplar gave lactic aldehyde. These three last bodies are formed by the assimilation of carbon dioxide; they vary with the species like all fermentation compounds produced by bacteria and like them they evolve simultaneously towards the synthesis of sugars, fats or nitrogenous matters and aromatic nuclei.

II. — In order to explain the formation of immediate products resulting from assimilation of carbon dioxide by green plants, it becomes necessary to attribute a fundamental part to hydroxylamine. The existence of this base in leaves is made certain:— (1) By the transformation of ammonia into oxygenated nitrogen compounds and *vice-versa*, which takes place normally; (2) by the constant presence of free nitrous acid and, very frequently, of hydrocyanic acid, two derivatives of the oximes. Hydroxylamine, acting first as a base, fixes the Co^2 and forms a compound which decomposes into nitrous acid and glycolic aldehyde:—

$$2\ CO_2\ NH_2\ OH = CH_2\ OH - CHO + NO_2\ H$$

These two compounds were found in elder leaves by the author. The acetic aldehyde, very abundant in green leaves can arise either from glycolic aldehyde by reduction from the glycotic aldehyde, or by the direct oxidation of the alcohol. It can serve as a base for the formation of another series of bodies by combining with the hydroxylamine, passing through the oximes

The glycolic and lactic aldehydes may give rise to other combinations either, by hydration or condensation, by oxidation or by new combinations with hydroxylamine.

As for hydrocyanic acid and acetylmethylcarbinol, they can be considered as already being elaborated products.

All the transformations considered so far can only be made with the help of the energy furnished by the combustion of respiration. They are therefore widely distributed among the living cells, but they are hidden by the inverse phenomenon of respiratory combustion, which liberates a volume of CO_2 which is much greater than that which is assimilated by way of reduction.

267 - **The Secretion of Invertase by Plant Roots. — Experiments with *Pisum arvense* L. and *Zea Mays.* L.** — KNUDSON, L., in *American Journal of Botany*, Vol. VII, No. 9, pp. 371-379, Tables 4, figs. 1, bibliogr. of 9 works. Brooklyn, N. Y., Nov. 1920.

The plants under investigation were grown in water cultures under sterile conditions, that is, with the root system in a nutrient medium free of micro-organisms, and the seed removed from contact with the culture solutions. The PFEFFER nutrient solution was used, with the substitutions of dibasic for monobasic potassium phosphate. The following formula was employed:— calcium nitrate, 4 gm.; potassium phosphate, 1 gm.; potassium nitrate, 1 gm.; magnesium sulphate 1 gm.; potassium chloride

0.5 gm.; ferrous chloride, 50 gm. and distilled water 6 litres. To this sucrose was added, when required.

With the Canadian field pea (*Pisum arvense* L.) the culture vessels were pyrex flasks of 1 litre capacity and the quantity of nutrient solution was 1050 cc. Sterilisation was effected by autoclaving at 15 lb. pressure for 30 minutes and seeds were sterilised by the use of calcium hypochlorite for 1 hour. The plants were grown in a greenhouse at an average temperature of 70° C. Only those cultures that proved to be sterile were analysed. The results indicated that in each of the culture solutions containing sucrose there was an appreciable gain in reducing sugars, but the gain is relatively slight as compared with the total amount of sucrose present, the maximum gain being only $^{1}/_{15}$ of the sucrose present. Experiments with both *Pisum arvense* and *Zea Mays* in slightly modified nutrient solutions with ferric chloride in the place of ferrous chloride, showed relatively the same results.

In order to determine whether or not the enzyme invertase was present in the culture solution, 500 cc. of the solution was incubated for 14 days, at 32° C., with toluene used as an antiseptic agent. No increase in reducing sugar was found at the end of that period, except in one single case with *Zea Mays*, due undoubtedly to the enzyme invertase derived from *Penicillium* contamination.

Further experiments confirmed these results, and the author concludes therefore that the reaction of the culture solution is such as to be without influence on the sucrose. All incubation experiments also yielded negative results with respect to the presence of invertase. The author considers that there is only one explanation to account for the accumulation of reducing sugars, namely, the excretion of reducing sugars by the roots. In support of this idea, the following experiment is described. Three maize plants which had grown for 30 days in PFEFFER'S solution (each weighing approximately 18 gm), were removed, and after washing the roots, were transferred to culture vessels so that roots alone were bathed in a 4 % solution of sucrose. After 16 hours, the plants were again transferred after rinsing, to another culture vessel containing distilled water, and allowed to remain there 7 hours. The total volume of distilled water was then reduced by evaporation to 100 cc and this was analysed for reducing sugar, and the determinations gave 14.5 mgm. of the said sugar.

268 – **Effect of Premature Freezing on Composition of Wheat.** — BLISH, M. J. (Montana Agricultural Experiment Station) in the *Journal of Agricultural Research*, Vol. XIX, No. 4, pp. 181-188. Tables 4, bibliogr. of 7 works. Washington, D. C, May 15, 1920.

A report of an investigation concerning the effect of premature freezing on the more important chemical constituents of the wheat kernel, particularly the nitrogen compounds from which the gluten is formed.

In order to obtain samples of sound and frozen wheat of the same varieties, and grown as nearly as possible under the same conditions, plots were seeded at intervals of a week, for about 2 months, the wheat in all plots being cut either shortly after maturity, or immediately after the first killing frost. A series of plots was seeded in 1917, and 1918. All plots were irrigated in mid July and at obviously different stages of development. The wheat from the 1917 series was brought to the granary shortly after cutting and thrashed when dry enough to permit. The grain from the 1918 series, however, was allowed to remain in the field, after it was cut and shocked, and it was therefore subjected to several months of severe weathering in the field. A chemical analysis of the grain from the two series indicated the appreciable effect on the biological properties apart from the effects of freezing. It was noted that the nitrogen in the α-amino and amide forms as well as the total non-protein nitrogen ran higher in the mature samples of the 1918 than in the corresponding samples of the 1917 series. In a previous paper the author has shown that while the proteins themselves are completely removed in the method of determining non-protein nitrogen, there still remain some peptids in the solutions (1) Therefore the figures for α-amino nitrogen reported include the " exposed " α-amino nitrogen of these peptids as well as that of the amino-acids.

A brief study of the effects of premature freezing on the carbohydrates of the wheat kernel showed that the percentage of reducing sugars, non-protein nitrogen and acid-reacting constituents evidently increased with the severity of freezing. The α-amino fraction of the non-protein nitrogen was also considerably higher in the frozen than in the sound wheat.

269 - **The Influence of Light Rays on *Azotobacter*.** — KAYSER E., in *The Comptes rendus de l'Académie des Sciences*, vol. CLXXI, No. 20, pp. 969-971. Paris, Nov. 15, 1920; vol. CLXXII, No. 3, pp. 183-185. Jan. 17, 1921.

I. — The influence of different light rays on bacteria has already been the object of many investigations. The complete destruction of the micro-organisms, the loss of chromogenic power, and the attenuation of virulence, sometimes the intensification of certain properties as found in the experiments of ENGELMANN with *Bact. photometricum*, have all been observed.

The author has studied this action with *Azotobacter agile*, which is characterised by great motility, the formation of pigment and fluorescence. He again found that the maximum of nitrogen is assimilated with yellow and green and corresponds to the maximum of sugar that disappears, and at the same time to the maximum mass of bacteria collected on the filter. With regard to this, one cannot speak of mathematical proportion (the amount on the filter weighed 71 mgm. for green, 69 mgm. for yellow, 51 mgm. for violet, and only 42 mgm. for red) for in a biological phenomenon, many factors intervene in a more or less tangible way. It is in the blue that the maximum quantity of nitrogen per gramme of sugar decomposed is assimilated. The experiments show, then, besides the influence of radiation, that of the food hydrocarbon, and of the microbial mass. On the other hand it is known that the age, and concentration of the microbes and the temperature also come into play.

---

(1) See *R.* June 1918, No. 688.

Tests now in progress will show if luminous induction could confer permanent properties on the nitrogen fixer and give rise to new types. With regard to this the researches of MM. RICHET and CARDOT have shown the remarkable adaptability of micro-organisms to antiseptics. The action of light often gives rise to the production of antiseptics in the environment and when the microbes become accustomed to these modifications they may acquire characters very favourable to the assimilation of nitrogen under agricultural conditions.

II. — In the preceding note the author has shown that *Azotobacter* is sensitive to various light rays and that yellow rays above all others favour the nitrogen fixation.

The author has tried to solve the problem as to whether this property remains constant during a series of generations and what is the action of light on generations of different ages always cultivated under similar conditions of lighting and of the same origin.

The experiments have shown that the total quantity of nitrogen assimilated was always greater with the 3rd generation. The rate varied with the coloration to which the culture was submitted, and the difference between the two generations, very marked with white light, was relatively small for yellow and blue. It is know, however, that with the number of generations the cultures in white light become coloured less and less and more and more slowly; coloration persists with all other colours with varying shades. The nitrogen fixed per unit of carbohydrate decomposed is least with the yellow where the microbe works least economically; the power of assimilation is specially diminished in the 6th generation, with green, white and black. The proportion of glucose consumed is always greater in the 3rd generation, except with blue, for with this colour the 6th generation destroys more mannite than the 3rd generation.

The proportion of carbo-hydrates consumed is highest for cultures exposed to white and yellow light, and is smallest with green; in the presence of glucose, mannite is only slightly attacked. It is due to this colour that the difference between the total of nitrogen fixed by the 2 generations is much greater than for blue and yellow.

Experiments in progress are intended to show whether, under the influence of light, bacteria can be made to acquire their old properties, or even to strengthen them, and also to ascertain to what extent the assimilating power of these bacteria can be diminished.

270 - **Studies on the Root Nodule Organisms of the Leguminous Plants, at the Agricultural Research Institute, Pusa.** — IOSHI, N. V. (First Assistant to the Imperial Agricultural Bacteriologist, in *Memoirs of the Department of Agriculture in India, Bacteriological Series*, Vol. I, No. 9, Pl. 9, tables 12. Calcutta and London, July, 1920.

A report of some interesting work carried on in the laboratory at Pusa to investigate the question of species by cross-inoculation of the organism from root nodules of one plant on another, and the nitrogen fixing power of the organism independent of the plant.

The culture medium employed had the following composition:— soil extract 1000.0 cc; mannite 20 gm.; potassium phosphate 0.5 gm.; agar

20.0 gm. The soil extract was prepared by heating 1 kilo of Pusa soil with 1500 cc. water in the autoclave at 120° C for 20 minutes, allowing it to settle, and filtering off the supernatant liquid.

At first several strains of the nodule organism from cow-pea (*Vigna Catjang*) were isolated, and two were selected for cross-inoculation purposes and to test their nitrogen fixing power. A second experiment was arranged for a greater number of organisms to be cross-inoculated on pea (*Pisum sativum*), math (*Phaseolus aconitifolius*) and gram (*Cicer arietinum*), while a third experiment was arranged to see whether the results could be confirmed by reinoculation of some of the organisms on pea.

The results of the latter 2 experiments show that substantial increase in growth of roots and of the whole plant results from inoculation of root nodule organisms although not always accompanied by nodule formation. The absence of these nodules was thought perhaps to be due to the possibility that nitrogen might be fixed by the organisms in the sand independent of the plant or that the organisms might be present in the roots, but in less virulent form. No organisms were however discovered in the sections of roots examined.

Further experiments were made with *Pisum sativum, Phaseolus aconitifolius, Cicer arietinum, Zea Mays, Avena sativa* and *Triticum vulgare.* It was at once evident that the plants which received nitrates were the best. The leguminous plants inoculated with their own organisms come very near these in quality, and next in order come the cross-inoculated, the *Azotobacter* inoculated, and those grown in porous pots. The effect of nodule organisms on the graminaceous plants is also marked ; of course no nodules were found on their roots.

The results of cross-inoculation showed the following positive results :— *Vigna Catjang* × *Phaseolus ; Pisum sativum* × *Phaseolus ; V. Catjang* × *P. sativum ;* and *Phaseolus* × *P. sativum.* The organism from *Cicer arietinum* has not been found to cross-inoculate *Phaseolus* and *P. sativum* and *vice versa.*

In order to detect the presence of ammonifying and nitrifying organisms, a portion of the sand from the inoculated and uninoculated pots was separately inoculated in each of the following culture solutions : 1) peptone water ; 2) OMELIANSKI solution. After 4 weeks inoculation, nitrites or nitrates could not be found in No. 2 solution showing the absence of nitrifying organisms ; and only after 72 hours was about 4 mg. of ammonia found in No. I solution.

The author desires to point out that the chief reason why the legume nodule organism is not recognised to have been isolated from the soil is that statements have been accepted as correct without thorough examination ; for example, that a nodule organism does not generally grow in ordinary nutrient media and that the organism fixes considerable quantities of nitrogen in culture flasks. Thus when any organism closely resembles the nodule organism and yet does not fix nitrogen in large quantities in the laboratory, the tendency is to take it as altogether different. To prove the inadequacy of this system of reasoning, the author experimented with one of the said organisms and with the same morphological characters as the nodule organisms, and cultures were then inoculated into sann-hemp (*Crotolaria juncea*), arhar (*Cajanus indicus*), cow-pea (*Vigna catjang*) and math (*Phaseolus aconitifolius*). These plants were grown in pots of sterile sand and all showed nodule formation when uprooted at the end of the experiment.

None of the media tried can be called absolutely specific, but an experiment was devised to test which gives the highest number of nodule organisms out of the total number. Nodules of val (*Dolichos Lablab*), indigo (*Indigofera arrecta*) and *Vigna Catjang*, were inoculated into these media. The highest number of nodule-organism colonies were found in the soil extract + mannite + agar and the lowest in the levulose agar (GREIG-SMITH) but this was particularly free from extraneous organisms.

The chief function, therefore, of the root nodule organism appeare to be nitrogen fixation whether within the nodules or outside. The fact that there is no residual nitrogen in the case of the nodule organism as contrasted with *Azotobacter* suggests that the fixation of the nitrogen by the organism and assimilation of the same by the plant with and without nodule formation go on approximately at the same rate. This implies the necessity of the removal of the products of metabolism by the plant before further nitrogen fixation by the organism can take place. Further experiments are necessary to furnish final evidence on this point.

271 - **The Work of the Central Station of Genetics (Experiment Station for the Improvement of Agricultural Plants) at Gembloux, Belgium.** — JOURNÉE, G. and LATHOUWERS, V, in *Annales de Gembloux*, Year 26, Part. 12, pp. 559-566. Brussels, December 1920.

The Experiment Station for the Improvement of Agricultural Plants, attached to the Gembloux Agricultural Institute, carries out its programme of work on the following main lines:—

I. — Experimental selection, and crossing combined with selection.

II. — Cultural tests of the new types thus obtained in the different agricultural regions of the country, with the object of testing their practical value as regards the local agrogeological and climatic conditions (Regional Research Centres).

III. — Enquires as to the value of the principal varieties now cultivated in Belgium.

SELECTION — *Cereals.* — The work of selection is carried out as follows:— From among the descendants of one parent plant those individuals are chosen that possess to the greatest extent the characters to be preserved. The group of individuals thus isolated forms " first choice ", while the rest are the " second choice ". The following year, the offspring of the "*first choice*" are also divided into *first choice* and "*second choice*", and the seed of the best individuals of the latter serve for the " first multiplication ". The best specimens thus obtained are used in their turn for subsequent " multiplications ', whereas the descendants of the " first choice ' continue to be divided into "*first choice*" and "*second choice*'.

The yields of the selected plants, as well as those of the " multiplications ", are analysed with great care, special attention being paid to characters that affect productivity (number of seeds per plant, weight of 100 or 1000 caryopses, % of seeds yield per *are* etc.). These details, in addition to the continual careful observations made during the growing season with the object of studying the resistance of the plants to cold, disease, and lodging, their early ripening, etc., furnish data for the subsequent discarding of the inferior plants, and the isolation of the best.

The improvement of wheat and oats was begun in 1913-1914, and, in 1919-1920, there were 103 pure lines of wheat and 77 of oats being studied. In 1919, the work of improving spelt and winter barley was commenced: 202 parent spelt plants and 172 of barley were examined comparatively.

The parent plants were chosen from plots sown with the seed of varieties from different districts; the examination of the plots will at once show that these varieties are far from being homogeneous, and should rather be regarded as associations of numerous varied forms, many of which are distinguished from one another by constant and well-defined characters.

The Station proposes to separate these associations by isolating pure lines and propagating the best types. Much has already been done in this direction, especially in the case of wheat. Large and complicated crossing experiments are also being carried out with the latter. Crosses between several varieties of wheat have ben made since 1918, and repeated in the following years, in order to obtain types with a higher yield, but at the same time resistant to cold and maturing early.

In 1919, some pure lines of wheat showed " speltoid " mutations, which were isolated, and have now reached the 3rd generation.

Potatoes. — At present 81 lines are being studied, especially as regards high starch content, resistance to disease, cooking properties, and yield. Some already show a good combination of these characters.

Sugar Beets. — In 1915, a " first choice " was made of 100 plants which were selected for shape, weight, and the high sugar content of the root. Then alternate generations of the seed-beets and the roots of the best lines were kept. Little work has however been done, on account of lack of men.

REGIONAL RESEARCH CENTRES. — In 1919, the advisability was discussed of creating branch Stations, or phytotechnical Stations of secondary importance, for the different agricultural regions of Belgium. Three such Stations have already been established, at Brosbeke. (East Flanders), Clavier (Condroz), and Carlsbourg (Ardennes). The duties of these Stations are: —

(1) To study the behaviour, in different soils and climates, of the varieties obtained at the Central Station;

(2) To compare these varieties with the best local varieties;

(3) To try to introduce and acclimatise foreign varieties, especially those coming from N. Holland, or obtained at Svalöf:

ENQUIRIES. — In 1919-1920, at the request of the Central Station, and under the auspices of the State Agriculturists, a census was taken of the varieties of cereals cultivated in Belgium.

The Station keeps constantly in touch with foreign scientific work connected with the genetics and improvement of agricultural plants. All the principal journals dealing with genetics, and the best works that have hitherto been written on the subject of heredity can be consulted at the Station.

In order to facilitate research, all the data have been entered systematically on a card-index.

272 - **Behaviour of Certain Hybrids of Oats and Spring Wheat at Rampart Station, Alaska.** — GASSER, G. W., in *Report of the Alaska Agricultural Experiment Stations*, 1918, pp. 41-47. Washington, Sept. 1920.

OATS. — Hybrid No. 51a, F_2 (Hull-less No. 304-2 × Norwegian No. 117-3 effected with a view to producing a hull-less oat ripening early. As in the F_1 generation, many of the heads presented the unusual feature of bearing both triflorous and polyflorous spikelets, and both hulled and hull-less kernels. The glume were either white, black or dark grey.

One of the chief aims has been successful, namely, earliness. They ripened in 88 days (3 days less than the Norwegian parent from which earliness was inherited).

SPRING-WHEAT. — No. 30a, F_3 (Chogot × Marquis). A true cross inheriting qualities from both parents:

In the all-important quality of earliness it holds an intermediate position, ripening on August 27 (14 days later than the earliest plant of Chogot); Marquis did not ripen either in 1918 or in 1917.

273 - **Improvement by Selection of Yellow Flint Maize in Mauritius.** — AUCHINLECK, G. G., in *Department of Agriculture, Mauritius, Bulletin* No. 18, pp. 1-19, pl. 5, Port Louis, 1920.

A lowering in the number of rows of grain on the ear of maize has a decided influence on the yield. The author considers that the 16 and more types are the most common, and on the other hand, ears possessing 14 rows or less of grain are less frequent.

Although the character in question may be largely influenced by surrounding conditions and present marked fluctuations, it appears, however to depend on elements both fundamental and hereditary.

Evidence that it will eventually be found possible to obtain each type " row true " by means of more careful isolation in the field is afforded by consideration of the marked increase in the frequency of ears of 16 rows and more, which has followed from sowing seed derived from high-rowed ears, and the large number, on the other hand, of ears possessing 14 rows or less, which resulted from planting ears of a small number of rows.

The results so far obtained indicate that ears possessing 12 rows of grain, give a small yield in general (weight of ears and yield per arpent) (1), whilst the 18-rowed and 16-rowed types are robust and good yielders in the field.

The Yellow Flint Maize may therefore be improved by selection based on the character " number of rows of grain per ear ".

274 - **Inheritance of Characters Resulting from a Natural Cross between Two Varieties of *Dolichos Lablab*.** — HARLAND. S. C, in *Journal of Genetics*, Vol. 10, No. 3, pp 219-226 London, Oct. 1920.

Dolichos Lablab L. is naturally self-fertilising ; dehiscence of the anthers takes place at least one, and sometimes 2 days before the flowers open.

The following characters have been studied in these experiments: 1) habit of growth; 2) anthocyanin colouration of flower, seed, and vegetative parts.

HABIT OF GROWTH. — The various races of *Dolichos* may be divided into two main groups, according to whether the growth habit is indeterminate (climbing) or determinate (dwarf or bush). The latter are so called from the fact that the main axis terminates in an inflorescence after from 4 to 8 nodes have been developed and the secondary branches also terminate in flower clusters. With the cross St. Vincent Bush White (bush) × Vilmorin's Stringless (climbing) the following results were obtained :— F_1 hybrids possessed the indeterminate habit;

F_2 : Out of 389 plants, 298 were indeterminate and 91 determinate; ratio 3 : 1.

F_3 : out of 17 families grown from F_2 indeterminates ; 4 bred true to indeterminate, and 13 families segregated into indeterminate and determinate in the 3 : 1 ratio.

Ten families were grown from F_2 determinates ; all these bred true.

From these results it may be concluded that the determinate and indeterminate habits of growth in *Dolichos Lablab* constitute a simple allelomorphic pair of characters, with complete dominance of indeterminate habit. The factor for indeterminate habit is denoted by the symbol I.

COLOURATION OF FLOWERS. — The following conclusions may be deduced from the hybridisation experiments evolved to this end :—

1) Two factors are concerned in the production of the purple colour of the flower ; these may be denoted by the symbols C and R ;

2) In the absence of either factor, the flower is white ;

3) According to this the cross St. Vincent Bush × Vilmorin's Stringless is of the nature cR × Cr. The genotypes appearing in F_2 will be as follows :—

---

(1) Arpent = 1.043 acres (*Ed.*)

Homozygous			Heterozygous			
Genotype	No	Colour	Genotype	No	Colour	Behaviour In F_3
			CR Cr	2	purple	3 *p* : 1 *w*
CR CR	1	purple	CR cR	2	purple	3 *p* : 1 *w*
Cr Cr	1	white	CR cr	4	purple	9 *p* : 1 *w*
cR cR	1	white	Cr cr	2	white	All white
cr cr	1	white	cR cr	2	white	» »

This hypothesis is confirmed by the experimental results:

1) The ratio of purple to white in F_2 is 484 : 342 (9·7),

(2) The 25 F_2 whites gave in F_3 only whites;

3) Of 65 families from F_2 purples, 35 exhibited the 9 : 7 ratio, 25 the 3 : 1 ration, while 5 bred true (all purple);

4) White flowered plants, from F_2 or F_3 families, invariably bred true.

CORRELATION OF FLOWER COLOUR WITH ANTHOCYANIN COLOURATION OF SEED AND VEGETATIVE PARTS — The purple flowered cross between the 2 white flowered forms St.. Vincent Bush and Vilmorin's Stringless exhibited:

(*a*) purple colouration of the nodes of the main axis, and to a slight extent, of the veins of the leaf.

(*b*) black seeds. In subsequent generations, all plants with purple flowers possessed purple nodes and *vice-versa*

One of the parents, St Vincent Bush, is entirely devoid of anthocyanin colouration, including the seeds which are cream. The other parent, possesses an extremely minute degree of pigmentation of the stipular hairs, which can only be detected microscopically, the seeds are, however, of a purplish brown colour.

On flower colour alone, it is not possible to distinguish between the phenotypes, Cr cR and cr, for they are all white flowered. The factor C, however, produces visible effects in other parts of the plant body and the combination Cr may thus be easily distinguished from cR and cr, (these two last are so far as we know, indistinguishable).

The factor C produces a purplish brown anthocyanin colouration of the seed coat and a minute amount of pigmentation of the stipular hairs.

The F_1 of the cross Cr × cR is coloured purple in the region of the nodes along the main axis, while the seeds are black. In subsequent generations, all plants with both C and R, have black seeds and purple nodes. It thus appears that the combination of C and R, determines a particular mode of distribution of anthyocyanin pigmentation in the plant body. The factor C determines the production of anthocyanin in seed and in stipular hairs; the factor R combined with factor C converts the white flower into purple and brown seed into black, at the same time extending the pigmentation to include the nodal regions of the stem.

The cross St. Vincent Bush × Vilmorin's Stringless may be represented thus:

PARENTS	*St Vincent Bush*	×	*Vilmorin's Stringless*
	c R		**C r**
	White seed White flower Green plant body		Brown seed White flower Purple stipular hairs

*F*1	**Cc Rr**
	Black seed Purple flower Purple nodes

*F*2 . . 9 **CR**	3 **Cr**	3 **cR**	1 **cr**
Black seed Purple flower Purple nodes	Brown seed White flower Purple stipular hairs	White seed White flower Green plant body	White seed White flower Green plant body

It is clear, therefore, that the best classification of the plants could be effected by examining the seed colour.

In conclusion, it may be taken that 3 Mendelian factors govern these characters:—

I The factor for indeterminate habit.
C The factor for purplish brown seed coat and purple stipular hairs.
R A factor which has no effect except in the presence of C, when it converts white flower into purple, brown seed into black and causes pigmentation of the nodal regions.

275 – **"Kumpta" Cotton and its Improvement in India by Selection and by Crossing Combined with Selection.** — KOTTUR, G. L., in *Memoirs of the Department of Agriculture in India, Botanical Series*, Vol. X, No. 6, pp 221-272, Pl. I-VII. Calcutta, October 1920.

"Kumpta" cotton (which is also known under the names of "miraj", "bail-hongal", bogalkot, and "westerns"), is a type of *Gossypium herbaceum*. It is grown over a very large area in the southern Maratha Country, in Mysore and the Nizam's Dominions, and especially in the Dharwar District.

This type of cotton is not a pure type, but consists of a large number of distinct strains with different anatomical and physiological characters. In other words, "Kumpta" cotton is what is called in genetics a "mixed population".

Let us take, for instance, the number of monopodia which was determined for 979 plants, and may vary from 1-8. The said plants are divided, as follows, as regards the number of monopodia:

Number of monopodia	Frequency
1	0
2	82
3	**268**
4	199
5	**311**
6	93
7	17
8	9

If on a straight line the abscissae 1-8 are marked at equal intervals, and ordinates drawn, so as to form a vertical rectilinear segment corresponding to each pair of these numbers, and of a length proportionate to the number of plants having this determined number of monopodia, on joining the end of these segments, a curve is obtained with two points corresponding to the numbers 3 and 5, and separated by a depression corresponding to the number 4

This is a biometric system for the analysis of intermixed strains, and is based on the variability of their characters If the strain is pure, there will be but one point, on the other hand, if it is mixed, the number of points may exceed 1

In the present case, which refers to the number of monopodia there are, as has already been said, 2 points.

Similar conditions are observed as regards the length of the central leaf lobe (of 1000 leaves).

Length of central lobe in mm	No of times occuring (frequency)
39–42	22
42–45	21
45–48	77
48–51	**250**
51–54	158
54–57	**222**
57–60	120
60–63	62
63–66	9
>66	39

The curve obtained by joining these data would thus have 3 points

As regards the ginning percentage we find. (See table pag 293)

In this case, the curve would have 4 distinct points: in the tables, the figures corresponding to the latter are in thick type.

The above-mentioned data, as well as other facts stated by the author, show that " Kumpta " cotton consists of a complicated mixture of strains. For this reason it is capable of improvement by selection, and by crossing

Ginning percentage	Frequency
18 %	1
19	2
20	9
21	12
22	19
23	11
24	14
25	9
26	6
27	7
28	1
29	8
30	1

combined with selection. Therefore the article analysed gives the results of a series of experiments carried out for the purpose of obtaining (by individual selection and combining the best characters) a type of cotton possessing the following qualities in the highest degree:

1) Large number of fruiting branches (sympodia). When the number of these is large in comparison with that of the monopodia and of the axillary shoots, the number of the bolls, and hence the yield, is increased.

2) Rapid growth, early flowering and ripening, so that the cotton can be collected in two pickings, thus avoiding the ante-monsoon showers of April and May, which often spoil the latter varieties and make the picking difficult.

3) High yield, long staple, high-ginning percentage.

SELECTION BY PURE LINES. — By this means, the following strains were obtained some of which were clearly superior, others inferior to the ordinary mixed type: " Dharwar No. 1 ", " Dharwar N. 2 ", and " Dharwar No. 3 ".

Dharwar No. 1. — Erect habit, with very few monopodia and axillary branches. The frequency curve for the number of monopodia, instead of having two points, has only one, which is a biometric proof of the homogeneous character of the selected plants.

As regards yield, " Dharwar No. 1 " is superior to ordinary " Kumpta " by 20 %. Another characteristic of " Dharwar No. 1 " is its earliness, for while " Kumpta " produces most of its flowers from the 11th to the 16th week, " Dharwar " flowers from the 10th to the 15th week, being thus a week earlier. The later the flowers are produced, the greater is the percentage of those that are shed and never develop into bolls as is shown by the first Table on page 294.

This clearly shows the advantage of early flowering.

Dharwar No. 2. — In " Kumpta " cotton there are both erect and bushy strains. The latter bear a large number of monopodia and axillary branches, which are more or less crowded about the central axis. The yield of these forms is naturally low. " Dharwar No. 2 " is a pure bred line of the

Month	« Dharwar no. 1 »		« Kumpta »	
	Number of flowers marked	Percentage of flowers shed	Number of flowers marked	Percentage of flowers shed
December	120	16.7 %	190	52.7
January	2370	14.8	2 500	36.0
February.	2480	69.0	5 210	79.9
March	50	100.0	20	100.0

bushy type. It cannot compare with ordinary " Kumpta ", and even less with " Dharwar No. 1 " in point of yield, but its ginning percentage is high, equal in fact to that of " Dharwar No. 1 ".

" Dharwar No. 2 " is of no commercial value, but is a proof of the heterogeneous composition of " Kumpta ". It may however possibly form the basis of future crossing.

" *Dharwar No.* 3 ". — This selection from " Kumpta cotton " has a long history dating back to 1901. In that year, a cross was made at Kirkee, by GAMMIE, between two strains of " Kumpta " (neither of them in pure line cultivation). In 1904, some of the most prolific of the plants thus obtained were again crossed, and the progeny were grown at Surat until 1908. The produce was only further selected by mass selection on the basis of ginning percentage and better staple. In 1908, all the plants, which were known under the name of " Kumpta Cross " were transferred to Dharwar, where they were studied and tested. It was found, that the type was not pure, and that it was every year losing its best characters, as the following Table clearly demonstrates.

Year	« Kumpta cross »			« Kumpta »		
	Yield of « kapas » (raw cotton) per acre in lbs	Ginning per cent	Value per *candy*	Yield of « kapas » per acre in lbs	Ginning per cent.	Value per *candy*
			Rs. (1)			Rs.
1908	624	27.1	275	—	—	—
1909	431	25.4	300	—	—	—
1910	516	30.3	300	546	25.5	805
1911	435	26.1	315	360	23.8	290
1912	586	28.0	305	759	24.8	290
1913	456	24.6	235	503	23.3	235
Average	508	26.9	288	549	24.3	280

Rupee = 1s. 4d. at par.

In the short period between 1908 and 1913, " Kumpta Cross " had deteriorated to such an extent, as to be inferior to ordinary " Kumpta ".

Therefore individual selection of " Kumpta Cross " was begun in 1913, and the seed has been maintained in this manner ever since. One of the products of this selection, " Dharwar No 3 " has a higher ginning percentage than " Dharwar No. 1 ", but it flowers a little later. It is, however, superior to ordinary " Kumpta ".

CROSSING AND SELECTION. — " Ghogari " cotton is a variety of *Gossypium herbaceum* which originated in the north of Gujarat. Its sole advantage is its high ginning-percentage (40 % and over). In length and quality of staple, vigour, productivity, etc , it leaves much to be desired.

Crosses were made between " Ghogari " and " Kumpta " with a view to endowing the latter with the character of high ginning percentage.

For a long time, these selections were unsatisfactory, as they continued to split, but finally 2 strains with fixed characters were obtained, " Dharwar No. 4 " and " Dharwar No. 5 ". These strains have the following characters :

Dharwar No. 4. — An intermediate type between an erect and a bushy plant. It however produces no axillary vegetative branches. It flowers early, like " Kumpta ", but is superior to the latter as regards yield and ginning %, but the staple is short.

Dharwar No. 5. — Is bushy in habit of growth, and late in flowering, therefore its yield is small. Its ginning percentage is high, and its staple good. It might also be useful for future crossing.

CONCLUSIONS. — Thus, 5 strains of cotton have been produced, 3 by pure-line selection, and 2 by selection out of a cross.

Dharwar No. 1. — An erect type, staple better than ordinary " Kumpta ", suited for the whole " Kumpta " tract.

Dharwar No. 2. — A bushy type. Staple better than that of common " Kumpta ". Does well in the south of the Belgaum district, and in centre of the Dharwar district (rainfall 750-875 mm.)

Dharwar No. 3' — Similar to No. 2.

Dharwar No. 4. — Semi-erect, an early type... Staple short.

Dharwar No. 5. - A bushy and late type, but with very high ginning percentage and good staple.

" Dharwar No. 1 " and " Dharwar No. 2 " were the two best types. The following Table gives the chief economic values of all 5 types.

Name of Cotton	Yield of « kapas » per acre	Ginning percentage	Yield of lint per acre	Value per *candy*	Value of lint per acre
	lbs	%	lbs	Rs	Rs
Ordinary « kumpta » .	467	25.5	119	500	75
« Dharwar no. 1 » . .	563	28.5	160	526	107
« Dharwar no. 2 » . . .	476	28.5	135	349	60
« Dharwar no. 3 » . . .	450	32.1	157	511	102
« Dharwar no. 4 » . . .	535	32.8	175	470	105
« Dharwar no. 5 » . . .	425	36.4	153	520	101

It is obvious from all these results, and from the descriptions of the types, that have been isolated by individual selection from " Kumpta " cotton, that we have in this cotton as it is usually grown, a mixture of a considerable number of strains differing in character of plant, in yield, in ginning percentage and in the quality of the lint. Some of these strains breed true, hence it is possible by the simple isolation of existing strains to get better types than those furnishd by the original variety. The qualities of earliness, yield, ginning percentage, and staple are in no way opposed to one another, and there is no reason why an early cotton should not also possess the other qualities. The latter are most nearly combined in " Dharwar No. 1 ". But some pure line strains with all the positive characters of " Kumpta ", and with a ginning percentage of over 36, have been obtained by the cross " Kumpta × Ghogari " This would lead to the belief, that it will be possible to go much further and combine in one strain this ginning percentage with the other desirable qualities occurring in " Dharwar No. 1 ". This will be the object of the author's further work on " kumpta " cotton.

276 - **Contribution to the Knowledge of the Phenomena of Self-fertilisation and Cross-Fertilisation in *Brassica Napus* L. var. *oleifera* Moenck.** — NILS SYLVEN, in *Sveri es Utsädesforenings Tidskift*, Year XXX, Part 6, pp 225-244, 9 figs. Malmo, 1920.

In 1918, the author began, at Svalöf a series of pure line selection experiments with colza (*Brassica Napus* L. var *oleifera* Moenck), taking as his starting point, 32 carefully chosen parent plants from a kitchen-garden near Petersborg, in the Province of Kulladal.

The parent plants had grown in the open country, and in contact with others differing from them botanically; they were thus exposed to cross-fertilisation, and as *Brassica Napus* according to the generally-received opinion is highly staurogamous, the descendants of the above-mentioned lines should have possessed the most varied and complicated forms.

Quite the contrary occurred however, the progeny were unaffected, being perfectly uniform and practically similar to their parents; this resemblance extending to all the most important characters: colour of leaves and stem; early ripening; length of petioles; tendency to flower twice; vigour of plant (resistance to lodging); type of inflorescence; colour of flowers; shape of fruit; formation of axillary buds.

The colour of the siliqua can serve as an instance.

In 1918, the 33 parent plants could be divided into 3 groups:

1) yellowish-green; Nos. 16, 20, 27.

2) dark-purple on part exposed to the sun; Nos. 17, 18, 19, 21, 23, 24, 25, 26.

3) pale purple on part exposed to the sun, Nos. 13, 14, 22, 25, 29 and 30.

The descendants of the 3 groups showed the characters of their group, to a large extent, in 1919. Thus, in the case of line 16 (of the 1st group), in only 25 plants out of 425, that is to say, in 5.9 % was the part of the siliqua exposed to the sun of a pale purple colour (character of group 3).

What occurred in the case of one line also took place to a greater, or less, extent in all the other lines, and as regards all the above-mentioned characters.

These phenomena are due to the fact, that colza, instead of being staurogamous, is on the contrary autogamous, as is shown by the anatomical and physiological examination of the flower. At the time when the flower unfolds, the four longest stamens cover, and entirely conceal the style, which at that moment, is of the same length as the two shortest stamens, these latter being bent slightly outwards. Then the style begins to grow rapidly, while the anthers of the four longest stamens open, and bend inwards, forming a sort of cap covering the pistil, and hindering the introduction of any pollen from without. Later on, when the stigma which continues to increase in length succeeds in passing out between the stamens, it cannot escape pollinisation. Cross-pollinisation is however only possible when the stigma, after having forced its way through the protecting stamens, remains freely exposed, but as by this time, it has nearly always been fertilised owing to the above-mentioned reasons, contamination action is almost impossible.

No change in this state of affairs can even be effected by honey-seeking insects, for the latter visit the already fully-open flowers which have been self-fertilised.

Colzas thus behave exactly as if they were autogamous plants.

On the other hand, as we have said above, their progeny is not entirely uniform ; among the descendants of line 16, there occur purple-tinted individuals, an almost certain sign that crossing has taken place.

The author's object in undertaking these series of experiments was to determine (taking the colour of the flower as a basis), the percentage of the cross-pollinations. A parent plant. No. 24, had yellow flowers ; 16 plants out of its descendants (100 in all) had yellowish-red flowers.

Some crossing experiments justify us in concluding that line No. 24 must be regarded as the F_2 generation of the natural cross yellow × red, and that yellow is a dominant colour as regards red. This being conceded, the number of yellow individuals met with in the offspring of the unisolated red parent may be regarded as the percentage of the crossing that took place.

The author has also been able to take the following characters as a means of determining the % of crosses.

1) yellowish-white colour of flowers (this is a repetition of what took place in the case of red).

2) Pure green colour of leaves (as opposed to green with traces of anthocyanin).

3) Light green colour of leaves (as opposed to normal green).

4) Twisting of axis of inflorescence.

The results of the experiments are summarised in the appended Table (page 298).

The difference observed between the unselected plants growing in the open field, and the selected plants is explained as follows :

1) Plants growing in an open field are exposed to all possible forms of crosses, and even to crosses with very different types ;

	Number of crosses in the open field						Number of crosses among selected plants		
	1915			1919			1919		
	minimum	maximum	average	minimum	maximum	average	minimum	maximum	average
Green colour of leaves.	59 %	16 9 %	10 2 %	—	—	—	0 %	8.4 %	2 0 %
Red colour of flowers	—	—	—	12.8 %	29 7 %	19.8 %	—	—	—
Yellowish-white colour of flowers.	—	—	—	22 6	22.6	22.6	—	—	—
Torsion of floral axis.	—	—	—	—	—	—	0	9.1	3 4
Pale tint of leaves	—	—	—	22.6	22.6	22 6	—	—	—

2) On the other hand, selected plants are already very uniform, and the possibility of the occurrence of new externally visible combinations is much reduced. In fact, it often happens, that the descendants of self-fertilised plants, like those of crossed plants, have the same characters.

It is however, of the greatest importance to know for certain the true % of crosses in the selected plants, in order to be able to form an idea of the possibilities of contamination to which the latter are exposed when it is wished to increase, in the same locality, the numerous types obtained from pure lines.

The experiments carried out in this direction in 1919-1920, would seem to show, that when the different types are sown in separate, but contiguous lines, the average number of crosses is 3 %.

When we consider that the number of crosses occurring in a typical autogamous plant like wheat is 1 %, we may well conclude that self-fertilisation is very common in *Brassica*, and a large percentage of the flowers are self-pollinated.

277 - **Crosses between Cultivated Strawberry varieties and Wild Varieties in Alaska to Obtain Hardy Commercial Berries.** — GEORGESON, C. C, and BENSON, C H, in *Report of the Alaska Agricultural Experiment Stations*, 1918, pp 22-23, Washington, Aug. 1920.

For a number of years much attention has been devoted to breeding hardy strawberry plants, suitable to the unfavourable weather conditions in Alaska.

Cultivated varieties of *Fragaria vesca* were hybridised with the two species of wild strawberry, *F. chiloensis*, a native of the coast region, and *F. platypetala*, a very hardy species of the interior.

About 3000 seedlings of these hybrids fruited for the first time in 1918. When fruit is produced the hybrid is numbered, and detailed records are kept of each plant as to date of blooming, character of flower, date of ripening the fruit, size and quality of the berry, prolificacy and vigour of the plant. All those with fruits that measure up to a certain standard of size, flavour, firmness etc. are retained, propagated and sent to other stations for test, and distributed among the settlers free of charge.

Fragraria vesca ♀ × *F. chiloensis* ♂. — Many of these hybrids were tested at Rampart and Fairbanks Stations. Although the mother parent (the cultivated berry) is not considered hardy, and the male parent *F. chiloensis* of the coast region is relatively tender, many of the hybrids, however, proved hardy to a certain extent in the interior regions.

The majority of hybrids produced large attractive berries, some of them of superior flavour, others insipid; as a rule they lacked colour and were soft, and, as a result, preserved with difficulty. They are suitable, therefore, for local consumption, but may not be used as commercial berries. There are only a very few hybrids with fruit in which large size, good colour, good flavour and firmness are combined.

Fragaria vesca ♀ × *F. platypetala* ♂. — A large percentage of the fruit of these hybrids was of good colour, good flavour and firm texture, but they were unfortunately too small and therefore unsuitable for commercial purposes. These hybrids are considered as distinctly hardy.

Another group of crosses has been made between the well-known Pacific coast variety Magoon ♀ with pollen from the wild plant of the interior (♂). So far as tested, this hybrid appears to possess all the desired qualities: large berries of deep red colour throughout, and firm enough to stand shipment. The flavour is good but not superfine.

This work will be continued with the hope of fixing on a single variety combining the qualities of size and colour of the berry with hardiness.

278 - **Results of Crossing the Raspberry Cuthbert with Salmonberry *Rubus spectabilis* in Alaska.** — GEORGESON, C C., and BENSON, C H, in *Report of the Alaska Experiment Station*, 1918, pp. 23-24. Washington, Sept. 1920.

In 1909, crosses were made at the Sitka Experiment Station between the salmonberry (*Rubus spectabilis*) and raspberry var. Cuthbert; the results were, however, unsatisfactory. On many plants blossoms were sterile and failed to set fruit; others were indifferent bearers, and none of them had any qualities that made them superior to good raspberries.

In 1918, however, one hybrid from a cross made in 1916 promised to be of value; the berries were salmon coloured, and of good size and pleasant flavour. This plant was a strong grower and showed some of the characteristics of both parents.

279 - **Red Clover Seed Situation in the United States.** — *The Market Reporter*, Vol. 1, No. 7, pp 97, 102-104, 107, 1 fig Washington, D C, Feb. 14, 1920.

No kind of seed probably has ever attracted the attention of two continents as much as the red clover seed in the years 1918-19. During these two years, the available supply has been lower than at any time since red clover has been extensively used in America. A shortage of some kinds of seeds would hardly cause any disturbance, but when it applied to red clover seed a general commotion was raised because of the great agricultural and economic importance of this crop. Recognising this fact, the United States Bureau of Markets assembled some of the data relative to red clover seed production, sowing requirements, imports etc., obtained from the Bureaux of Crop Estimates and Plant Industry and combined them with some of its own data.

The quantity of seed available in the United States in the beginning of 1920 appeared to be slightly larger than that available at a corresponding time in 1919, but considerably less than that of 1918, undoubtedly much less than normal, as indicated by the following figures showing production, seedsman's carry-over, and imports.

TABLE I. — *Production, carry-over and imports.*

	1917	1918	1919
	lb	lb	lb
Production, including all kinds of clover, chiefly red clover	89 280 000	71 820 000	65 940 000
Carry over July 1	15 533 691	4 177 647	1 858 560
Imports July 1, 1919, 1918 and 1917, to Jan. 31, 1920, 1919 and 1918, respectively	126 900	127 800	9 259 900
Total available supply (less exports) on Feb. 1, 1920, 1919 and 1918 respectively	**104 940 591**	**76 125 447**	**77 038 460**

Although exports of red clover seed are not taken into consideration in the foregoing Table, they probably would not affect the relation between the total supplies of each of the years, because the exports of all kinds of clovers (mostly alsike, but also including white and red clover) between July 1, 1919 and December 31, 1919, were only 13 000 lb. larger than between July 1, 1918 and December 31, 1918. This difference probably was more than offset by the estimated larger exports of red clover during January 1919, than during January, 1920.

On January 1, 1919 and February 1, 1918, the stocks in the dealers' hands, less the carry over from the preceding July 1, and imports between that date and January 1, 1919 and February 1, 1918, respectively, were approximately 25 % of the total production of clover seed for 1918 and 1917. If this same percentage held true on February 1, 1920, it is estimated that the stocks in dealers' hands were about 27 500 000 lb. compared with 23 330 920 lb. on January 1, 1919, and 32 532 410 lb. on February 1, 1918; which figures for the latter dates were obtained from seed surveys.

The larger stocks on February 1, 1920 compared with the preceding year are considered due to the much larger imports since July 1, 1919 than for the same period during the previous year. The imports for the fiscal year ending June 30, 1920 are larger than those for any complete fiscal year since 1911, with 2 exceptions, as may be seen from the following figures:—

TABLE II. — *Imports for fiscal years ending June 30.*

	lbs.
1911	6 142 981
1912	19 674 155
1913	5 332 947
1914	5 920 934
1915	8 932 293
1916	32 508 537
1917	5 343 600
1918	768 300
1919	1 050 900
1920 (July 1919 to Jan. 1920 incl.)	1 259 900

It is interesting to note that approximately $^{7}/_{8}$ of the red clover that was permitted entry between July 1, 1919 and November 30, 1919, originated in Italy, and $^{1}/_{8}$ in France. The recent strike in the shipyards in Italy has delayed the arrival of seed bought by American seedsmen, but it is reported that after these belated shipments are received, there will be much more seed available from Italy and France.

The demand for red clover seed from European countries was not so urgent in the winter 1919-20 as in the previous year; fortunately Italy and France had surpluses of this seed to offer, and while undoubtedly the world stocks of red clover are much below normal at this time, they do not appear to be so short as they were the preceding year.

280 - **A New Process of Seed Preparation in Canada.** — EASTHAM, A. (Chief Seed Analyst), in *The Agricultural Gazette of Canada*, Vol. 7, No. 11, pp. 877-878, Ottawa, Nov. 1920.

A new method of cleaning and grading seeds and grain has been invented and patented by E. E. EDDY, formerly Chief Seed Inspector of the Department of Agriculture. The separation is made entirely on the basis of comparative specific gravity. This is effected by subjecting the stock to centrifugal action in the presence of a liquid which is of the specific gravity required for the separations desired.

A suitable material for making a liquid of the desired density is sodium nitrate, but other substances may be used. With seeds weighing about 60 lb. per measured bushel, such as alfalfa and clovers, a solution of about 1.2 specific gravity is required. By regulating the density of the liquid, the proportion of seeds which pass into the heavy and light separations is under complete control.

Tests of several samples of red clover showed a perfect separation of several kinds of the most common weed seeds, classed as noxious under the Seed Control Act. Almost equally valuable were the results in reducing the less harmful species.

Equally good results were obtained with alsike, alfalfa and timothy seed. Tests so far have been made mostly with small seeds. It is expected, however, that valuable results will be secured also with grains by removing barley and oats from wheat, oats from barley, etc. in addition to the separation of weed seeds.

The process is now being developed with the idea of putting it on a commercial basis, and should this be accomplished, there should be a great improvement in the purity and general quality of the seed available, and the seed growing possibilities both for small seeds and seed grain will be greatly increased.

281 - **Wheat Varieties at Verrière, France, 1919 and 1920.** — DE VILMORIN J., in *Comptes rendus de l'Académie d'Agriculture de France*, Vol. VI, No. 36, pp. 868-873. Paris, Dec. 1, 1920.

WEATHER CONDITIONS. — Crop *Season* 1918-1919: heavy rainfall from autumn 1918 to January 1919; fairly severe cold and snow in February; damp retarded spring sowings in March; dry weather up till July. The rains may be taken as too late as a general rule for spring crops

Season 1919-1920: mild winter: spring mild and premature. Somewhat cool at earing time; fertilisation hindered; heavy rains just before ripening; damp and cold retarded growth and favoured the attack of rust.

Result on Experimental Plots (25 *sq. m.*).

282 – **The Wheats of Cyrenaica.** — SCAETTA, H., in the *Giornale d'Agricoltura della Domenica*, Year XXXI, p. 35, 3 figs. Piacenza, January 30, 1921.

Libya possesses varieties of wheat, which acclimatised as they are to a hot, arid environment, can do equally well in other countries with similar conditions. For many years, Tripolitan wheats have been tested in Sicily, and some of them, having given excellent results, have been grown there of late fairly extensively.

The author mentions 3 of the best varieties of wheat from Cyrenaica —

" *Mogarbia.* . " — This is the most popular variety of wheat cultivated in the Colony. The grain is hard and the vegetative cycle rather short. The natives sow it in the second fortnight of November, and it ripens during the last 10 days of May or at the beginning of June. This wheat tillers well, especially if the ground is properly worked, and if it is sown in good time. The author has counted as many as 30 culms on one plant, all equally strong. The root system is not much developed, but this may be due to the traditional Arab method of cultivation (the grain is sown on hard soil, which is only ploughed to a depth of 10 cm. with a wooden plough).

" Mogarbia " is resistant to lodging, and seems immune to smut (*Tilletia Tritici*). It has the following characters:—

Ear black, awned, square; average number of fertile spikelets 18 to 20, minimum 16, maximum 24.

Spikelets with 4 or 5 fertile flowers. Average number of caryopses per head 67 to 68, minimum 50, maximum 95.

Glumes ovate-lanceolate, with very prominent keel, ending in a short pointed beak; 2 complete veins; brown border.

Pales oval, inflated, ending in very long awns, brown at the base and in the middle, and dark-red towards the top, section triangular at base; length 120-200 mm.

Caryopses of a fine wheat-yellow; of oval somewhat gibbous shape, ventral surface concave. Average length 8.1 mm.; average breadth

3 2 mm. Fracture glutino-horny, almost regular, edges rounded. Weight of 1000 caryopses 56 gm.

Culms strong from 1 m to 1.20 m. in height; on alluvial soils (such as those of the Bomba region, they are from 1.50 m. to 1.60 m. high.

Yield varies much according to the annual rainfall and the prevalence of the "ghibli" (wind from the desert) in spring. In good seasons, it produces 30 times the amount of the seed-corn, or even more

This variety should not be thickly sown; 35 to 45 kg. is cnough per hectare. All these data refer to the native system of cultivation.

"*Misko*". — This variety in its value and commercial qualities comes immediately after "Mogarbia". It is much grown throughout the Colony, and is particularly liked by the natives for bread-making. Its vegetative cycle is longer than that of "Mogarbia". The natives generally sow it in the second half of November, and it usually ripens early in June, 10 or 15 days later than the "Mogarbia" variety. The desert winds of the spring have a great effect upon the date of its ripening but all cereals mature very rapidly in Cyrenaica.

The characters of "Misko" are as follows:—

Ear red square pointed; average number of fertile spikelets 22; minimum 18, maximum 26

Spikelets with 4-5 fertile flowers; the number of caryopses varies per ear; minimum 35, approximate average 45-50, maximum 65

Glumes oval, keeled, terminated by short pointed beak. Two complete veins, edges light-red.

Pales oval inflated, light-coloured in the lower and middle portions, red in the upper, terminated by a long dark-red awn, triangular in section at the base. The longest awns are found, as in "Mogarbia," in the middle of the ear; they vary from 150 to 200 mm.

Carvopses of pale straw-colour; their dimensions vary according to their position on the ear, less distinctly convex than in the case of "Mogarbia"; ventral surface concave. Average length 1.7 mm. · average breadth 3.6 mm

Fracture. Glutino- starchy, very irregular with marked edges Weight of 1000 caryopses 60 gm.

Tillering remarkable.

Culms strong about 1.20 m. in height; in some parts of the interior, such as Ouadi Mhallag they even grow to 1.60 mm.

Yield. As compared with "Mogarbia", this variety is late, and therefore regarded as less resistant to adverse conditions, especially to the "ghibli". Its yield is very uncertain, varying from 5 or 6 to 1 to a maximum of 30 or 35. It is reckoned that the average crop produced is 15 times as much as the seed-corn. (These data also refer to the Arab methods of cultivation).

"*Screisra*". — This is a mediocre variety. It has, however, the advantage of having a short vegetative cycle, scarcely longer than that of barley The natives sow it during the last days of November and early in December. This wheat ripens in the first half of May. Its culms are from 80 to 90 cm. in height.

"Mogarbia" and "Misko" are very resistant to the "ghibli", whereas the Screisra variety, when scorched by the desert wind, sheds its caryopses.

283 - **The "Cignarellone" Wheat of Molise, Italy.** — Iosa, G., in *L'Italia agricola* Year LVIII, No. 1, pp. 1-7. 4 fig. Piacenza, January 15, 1921.

This variety of wheat, also called "cignarello mashio", or simply "grano maschio", is cultivated in a small, but characteristic, area of Molise, at an altitude of 600-800 m. above sea-level. This zone includes the districts of Barabello, Busso, Campobasso, Campodipietra, Colledanchise and Vinchiaturo.

The conditions favourable to the cultivation of "cignarellone" in the above-mentioned zone are the nature of the soil, which is of a clayey character, the climate (the mean rainfall being 443.6 mm from April to October, while the summer is relatively cool), the presence of artificial meadows planted with sainfoin, and often with lucerne and clover, and finally, the very careful preparation of the ground, which is usually hoed by hand. The fact that this wheat is greatly in demand for the manufacture of short and fine types of Italian macaroni, and for making cakes and biscuits has much contributed to its diffusion, not to speak of its high average yield, and its maximum crops, which are sometimes very heavy.

"Cignarellone" is a turgid wheat with the following principal characters:—

Roots.— Numerous, branched, strong, deep, from 25-30 cm. in length, if carefully extracted from the ground their diameter, at the point of insertion is from 2 to 3 mm.

Culms. — Well developed, very strong, empty near the ear, from 0.85 m. to 1.75 m. in height, with an average of 1.32 m. as determined by examining 97 plants Nodes 4 to 6 in number, large, prominent, internodes slight grooved. Diameter 5 to 7 mm. at 3rd internode.

Leaves. — Broad, fine, with long sheath, of a beautiful glaucous green colour, with waxy cuticle and conspicuous veins. The last leaf, together with the sheath embraces a large part of the upper internode.

Ears. — Large, of square pyramidal shape, compact, awned; colour pale yellow, deeply shaded with dark violet; 5 to 8 cm. in length (average of 95 ears, 6.51 cm.), bent over when ripe. There are, however, some ears that are completely yellow, and others with distinct black spots only on the two surfaces.

Axis of inflorescence and rachis, strong, very resistant.

Spikelets. — 23 to 27 in number, arranged in 2 rows with 3-5 fertile flowers.

Glumes. — Somewhat small, oval, inflated, keeled, with beak.

Pales. — Well developed, oval, the inner one with distinct long awn, the outer inflated, deep, sharp, awned.

The awns are 9 to 12 cm. in length, they are more or less separate, forming an angle of 15 to 45°; those at the base and top of the ear are nearly of the same length; they have a groove on the outer side.

Caryopses. — From 65 to 95 per ear on the principal culm; they are yellow, large, round, and have a wide distinct embryonic depression, and a deep ventral grove. Longitudinal diameter 6-8 mm.; transverse 4-5 mm. Fracture starchy, or glutino-starchy.

Weight of 1 000 seeds 70-80 gm.; volume 33 cc.; weight of litre 789 gm.

Tillering — Abundant, but the secondary culms frequently bear empty ears.

The examination of 97 plants gave the following results:—

Plants	with	1	complete	ear	78
»	»	2	»	ears	12
«	»	3	»	»	5
»	»	5	»	»	1
»	»	6	»	»	1

Ripening. — Rather late, from July 10-20, in normal years, at altitudes of 600 to 800 m.

Rust-Resistance. — Rather remarkable; resistance to lodging and grain-shedding very considerable. The culms do not lodge easily on very fertile soils rich in nitrogen. They even resist heavy storms. The ears never shed their caryopses, even if shaken.

Like all turgid wheats, "cignarellone" is a very exacting plant requiring the dampest and deepest soils possible; *e g* clays, sandy, or rich loams.

It does well if planted after sainfoin, lucerne or clover, or after a well-manured maize crop, but on sowing again on the same ground less satisfactory results are obtained.

The soil must be well prepared; it should be worked fairly deeply and very thoroughly. In the zones where "cignarellone" is grown hoeing is very advantageous to the crop.

Few varieties of wheat show themselves so susceptible to the direct application of complete fertilisers.

Experiments made in Molise in 1900-1901 by applying to the soil (after harvesting a lightly manured maize crop) 400 kg. of superphosphate per hectare at the time of sowing and 125 kg. of sodium nitrate in the spring gave 2413 kg. of cignarellone grain per hectare, whereas only 1637 kg. were obtained from the unmanured field.

This wheat should be sown early, at the end of October at latest and it should not be planted thickly, on account of its tillering propertities and the need of thorough hoeing.

When grown in a suitable environment, "cignarellone" gives a high and constant yield. In seasons when more delicate varieties succumb to great extremes of temperature, drought, or excessive damp, this wheat is remarkable for its resistance, and its relatively high yield. Farmers who have grown "cignarellone" for several years testify that its minimum yield has never fallen below 12-14 quintals per hectare, and that its maximum yield in good seasons has been as much as 25-30 quintals which is a heavy crop for the Apennine districts. The average yield is from 15 to 18 quintals per hectare, a production which is fairly certain.

The following results were obtained in the course of experiments made at Campobasso in 1920 (a bad year for wheat), both by farmers (1-3 experiments), and also in the field belonging to the Ambulatory Chair of Agriculture, Molise, " Cignarellone " being compared with other well-known varieties :—

No. of Experiment	Varieties of wheat	Production of grain in quintals per hectare
	Carosella " Todaro 91"	18.15
	Carlotta Strampelli	15.40
	Noé	14.70
	Blé de Mars local	6.90
	Cignarellone	18.90
	Carosella " Todaro 91 "	17.00
	Carosella local	12 10
	Cignarellone	16.60
	Carosella " Todaro 91 "	20.50
	Cignarellone	25.30
	Carosellone local	18 10
	Carosella local	18.60
	Cignarellone	19.10

The presence of some glutinous grains, and the fact that the fracture is starchy-glutinous would give cignarellone the character of a semi-hard wheat.

There are, however, different types in which sometimes the starchy grains, at others the glutino-starchy grains are in excess Experts attribute this fact to the soil on which the wheat has been grown, but very probably it is also due to confusion between the races.

The following percentages have been obtained in analyses carried out at the " R. Laboratorio di Chimica Agraria " at Avellino The sample came from the Experiment Field of the Ambulatory Chair of Agriculture of Molise, at Campobasso.

	Per cent.
Starch and sugar	71.02
Fats	1.60
Crude fibre	2.24
Ash	1.80
Nitrogenous substances	10.19
Undetermined substances	1.24
Water	12.82

The percentage of damp gluten in whole flour prepared in the laboratory was 21 %. Bread made with "cignarellone" flour is not of first rate quality, but the flour is greatly in request commercially for making "galettes" and biscuits.

According to the larger or smaller amount of grains with starchy fracture, this wheat is either used for semolina, to improve the colour of macaroni, etc., or is used alone in the manufacture of Italian macaroni of the best quality.

284 - **Field Experiments with Wheat in Western Australia 1912-1919.** — SUTTON, G. L. (Agricultural Commissioner for the Wheat Belt), in the *Department of Agriculture, Bulletin* No 63, pp 3-58 + figs 12. Perth, 1920

Report of experiments carried out at the Chapman and Merredin Experiment Farms dealing with: 1) depths of ploughing; 2) soil mulching; 3) fertilisers; 4) rotation; 5) wheat varieties; 6) rates of seeding.

There is a wide variation in the character of the soils at these two farms. At Merredin the soil is a rich clay loam and at Chapman a light-sandy loam. The 8 years average rainfall (April to November) in the former district was 989 (calculating that 100 points = 1 inch), and 1662 in the latter.

The methods adopted for all operations connected with the preparation of the land; planting and harvesting the crop, were similar to those adopted generally on a large scale.

I. PLOUGHING. — Conclusions drawn from results obtained by ploughing at 4,6 and 8 inches respectively are that on the fertile forest soils shallow ploughing is as effective as deep ploughing, but it is more important to work the land thoroughly than deeply. On lands less fertile, deeper and equally thorough ploughing is advisable.

II. SOIL MULCHING. — The object of this experiment was to determine how far and under what conditions the cultivation of winter fallowed land is profitable during the spring and summer On the light sandy loam the average results were considerably in favour of the cultivation after fallowing and before seeding, with a further slight advantage in favour of the cultivation after rain during the summer. On the rich clay loam, the average yields were remarkably similar, but somewhat, inconsistent as far as hay yields are concerned, for grain, cultivation was advantageous to a slight extent, at least in the spring.

III RATES OF SEEDING — A comparison between the use of 30 lb., 45 lb and 60 lb. per acre, each plot undergoing the same cultivation, manuring etc From the results obtained, it appears that the amount of good vigorous seed recommended to be sown per acre in the warmer portions of the wheat districts is 45 lb., on clean ground, and in the cooler districts or on weedy ground the amount should be increased 25 to 30 %. It should be noted that the seed used in these experiments was graded.

IV. FERTILISERS. — The prevailing conditions made it impossible to draw any but the most general conclusions from the results obtained on the light soil, but on the clay loam on the forest land in the Eastern Wheat Belt the following conclusions may be drawn: 1) that the application of superphosphate is essential for best and most economical results with wheat; 2) that for grain purposes an amount ranging from 56 lb. to 112 lb is most profitable in this particular climate, 3) that for hay the amount can exceed 112 lb with advantage; 4) that it is not advisable to use bone manure, rock phosphate or "guano" from the point of view of cost; 5) that liming is not profitable.

V. VARIETY TRIALS. — During the trials, a number of varieties were discarded, but of the original varieties retained at Chapman, in 1919, the Comeback var took the leading place for hay, and the Nabawa var. for grain According to the average for 7 years, the following list shows the order according to their percentage yields

Hay		Grain	
Florence	102	Florence	107
Comeback	100	Yandilla	103
Firbank	97	Comeback	100
Yandilla King	85	Firbank	87

At Meredin, a number of varieties have been discarded during the trials, but conclusions drawn from the results generally, point to the fact that "Federation" is to be recommended for early planting, where rust need not be feared; 'Gluyas Early' for mid season or main planting, and "Florence" for later planting. The early districts are those with comparatively light rains and warm weather in October, the mid season, those with heavier rains in October, and the late those with cooler weather and liberal October rains

VI. ROTATION. — On the light lands the following 4-course rotation is recommended as a result of various comparison trials. 1) Fallow; 2) Grain or hay crop, 3) Fallow, 4) Fodder crop (grazed); and until a reliable legume is found which can be used as a fodder crop, oats should be grown.

On the rich clay, the following 3 course rotation is advised namely; 1) Fallow; 2) Crop 3) Stubble. The results justify on economic ground, the practice of continuous wheat in the early years of pioneering.

265 - **Wheat Growing in the State of Parana, Brazil.** — *Lavoura e Criacão*, Vol. V, No 12, pp 284-285 Rio de Janeiro, Dec 1920

A report presented by M. ZDENEK GAYER, agricultural expert, to the "Serviço de Fomento agricolo" of Brazil.

In the State of Parana, wheat is cultivated in the municipalities of Arancario, Campo Largo, Curityba, Lapa, Palmeira, Prudentopolis, Rio Negro, and San José dos Pinhaes, and in the colonial groups of Rio Claro, Vera Guarany, Cruz Machado, Senador Corrêa and Yappo.

[284-285]

The soils which are preferred are red, compact, sandy clays; more fertile soils can be used if liberal dressings of organic manures are applied. The most popular varieties are "Barletta", "Rio Grande do Sul", "typique de l'Argentine" (of the municipality of Rosario).

The preparation of the soil is very rudimentary, and consists only of a shallow ploughing a little while before sowing, and it is due to this that many weeds come up and greaty decrease the crop.

Manuring is limited to the use of fertilisers, particularly phosphatic ones, amongst which superphosphate has given the best results and experiments on a small scale have shown that green manuring is very successful.

No sorting or disinfection of the seed is carried out. The seed is sown broadcast, very rarely with seed drills, in lines 15-20 cm. apart. About 60-140 kg. of seed is used per hectare. The larger quantities are used in late sowing on poor soils.

The average yield per hectare is 15-17 quintals of grain and 20-40 quintals of straw. The weight of a hectolitre is 80-83.5 kg. The vegetative period is 160-180 days. Reaping is done by hand, with the aid of a sickle. The cost of production of 1 quintal of wheat is 12 *milreis* (1 paper milreis = 6s. 8 ½d. at par).

The chief diseases of wheat in Parana are smut and rust.

286 - **The Green Manuring of Rice Fields** (1). — CHIAPPELLI, R., in the *Giornale di Risicoltura*, Vol X, No. 8, pp. 117-119. Vercelli, Aug. 31 1920

As the price of nitrogenous manures are now so high., the most economical way of applying nitrogen to rice fields is by green manuring with Leguminosae. The most suitable legume for this purpose is crimson clover which, possessing thick and rigid stems, decreases the tenacity of the earth, makes it very porous and, because it decomposes slowly, is effective during the whole period of growth of the rice. But the soil must be well prepared for the rice, must not be too cold, and should contain a little lime

The best time for sowing the crimson clover is a little before the rice is harvested, when the water has already been drained off, so that the seed can be sown on the still muddy soil. After the rice is harvested, an abundant dressing of basic slag or superphosphate is given, plus 5 or 6 quintals of calcium sulphate per hectare.

With old rice fields a light nitrogenous dressing such as 50 kg. of sulphate of ammonia or nitrate of soda per hectare would be useful It is most important to keep the furrows weeded and to deepen them if the rice field is old and "sortumose" (2) so as to prevent stagnation, this being one of the causes of failure with clover. Occasionally rolling may be necessary in spring.

---

(1) See *R.* April 1920, No. 417. (*Ed.*)

(2) When the rice is affected by "Sortume" the water rises from the subsoil to the surface soil. See *R* Feb. 1920, No. 173. (*Ed.*)

287 – **Irrigation of Potatoes.** — POWERS, W. L. and JOHNSTON, W. W., in *Station Bulletin No. 173* [*Oregon Agricultural College Experiment Station, Department of Soils*, pp. 5-28, tables XVII. Corvallis, Oregon, Aug. 1920.

Irrigation of potatoes has been carried out for the past 12 years at the Experiment Station, under conditions where rainfall for the growing season, April 30 to October 1, is 5 ½ inches, and the average evaporation about 24 inches for the period. The silt loam on which these experiments were conducted has a maximum capillary water content of about 34 %, an optimum moisture content of about 24 %, and a wilting point of about 14 %. The minimum moisture content under field conditions is 10 or 11 %

The most economical returns were secured with light frequent irrigations, which provide a uniform moisture content, for example, 1 inch every 10 days has given good results and is practicable, and much preferable to one heavy irrigation. The best results were obtained when the depth applied per season was 6 inches in wet seasons and 2 or 3 inches in dry seasons, while the maximum yields were produced with 3 or 4 inches in wet and 6 inches in dry seasons. Application of 9 inches depth decreased the yield.

Applying water in furrows 10 to 18 rods long has proved a suitable length of run for the silt loam. It was found disastrous during the experiments to neglect cultivation after irrigation. Water requirement can be greatly reduced in irrigation farming by keeping up a good rotation, including legume crops; by using good varieties; by maintaining a good fertility and tilth, and by irrigating at the right time in the proper amount.

Proper irrigation does not injure the palatability or marketability of potatoes and after 12 years there was little appreciable effect upon soil acidity or the content of available plant food. From the various determinations made, it appears that the moisture content is not appreciably increased by irrigation, except when applied in excess and then the potatoes had a less firm skin and were less solid. Proper irrigation decreased the percentage of culls

. In Central Oregon experiments, potassium sulphate increased the yield per acre inch from 24 ½ bus. on untreated to 39 bus. on treated land.

In Eastern Oregon irrigation of 5 to 9 inches depth per acre has given the best results in several of the potato producing sections, and frequently best returns have been obtained with 6 to 8 inches total depth, applied in 2 or 3 doses.

288 – **Use of Sour Clover (*Melilotus indica*) as a Rice Rotation Crop.** — MORSE, S. F., in *The Rice Journal*, vol. XXIII, No. 11, p. 46. Beaumont, Texas, November 1920.

This legume has been used successfully following fall-planted sugar cane and makes a winter growth of 18 to 24 inches in 3 to 4 months. The author recommends its use also as good crop between rice crops. *Melilotus indicus* will grow under very adverse soil conditions, and the seed is cheap. By double disking the rice stubble in September or October, and sowing broadcast 25 to 30 lb. of seed per acre, a good stand should be secured.

It is probable that simply scattering the seed over the stubble without harrowing would give good results, but this has not yet been tried. To be sure of a stand on land where this crop has never been grown, it is advised firts to inoculate the seed.

The above mentioned suggestion is made to encourage the use of this sour clover in preference to the white dutch clover (*Trifolium repens*) previously suggested by Hewes, owing to the uncertainty as to whether the latter would make enough winter growth to justify its use, except where the land was to be left lying out in pasture for 2 or 3 years.

289 – Growing of Sunflowers (*Helianthus annuus*) in Montana and Use as Silage (1).

— Atkinson, A., Nelson, T. B., Arnett. C. N., Joseph, W. E. and Tretsyen, O, in *University of Montana Agricultural Experiment Station, Bulletin* No. 131, pp. 3-29, tables 4, figs 4. Bozeman, Montana, April 1919.

A brief survey of the characteristics and history of the cultivated sunflower, followed by the results of tests on yields and methods of growing and feeding, as employed at the Montana Experiment Station.

Preliminary tests were carried out from 1915-18 inclusive, to find the crop yield A comparison of yields shows that while the heaviest yield is from the earliest planting, there are peculiar variations as the date of planting advances. Observations on the growth of the crop led the authors to recommend that planting should be made in the higher altitudes, where the season is short, and as soon as the ground has become warm and is in good condition in the spring. After planting in rows and drills at different distances apart, it was found that the largest returns, 44.1 tons per acre, was obtained from those planted in rows 36 inches apart, and in drills from 30 to 36 inches apart and 4 to 5 inches between seeds. In date-of-seeding tests, the largest yields were produced from the carliest plantings.

Dry land tests were made in 1918 on 13 different farms in 8 counties, and over 30 acres were planted. The average yield was 10.3 tons per acre. As this was a season of unusually low moisture precipitation, the authors consider it reasonable to conclude that sunflowers are a promising dry land forage crop.

Seed matured only one out of 4 years at the Bozeman Station. From observations, however, it appears that seed should mature regularly in the lower vallies where the temperature is higher and when there is a longer period free from frost.

Practical and experimental results up to date, feeding qualities, yields per acre and frost resisting qualities, all considered, were greatly in favour of sunflowers compared with other silage crops. It was successfully used in winter feeding practically with every class of farm stock, but it was found better to make a combination with dry roughage such as clover, alfalfa, or mixed hay.

---

(1) See *R.* April 1919, No 493, *R.* October 1920, No. 1008 (*Ed*)

Mammoth Russian sunflowers were successfully used for both soiling and silage purposes during the 4 years trial. Silage made from plants 30 % in bloom, compared favourably in digestible nutrients with maize silage made from immature maize:

Digestible Nutrients	Total dry substance	Crude protein	Crude fibre and nitrogen free extract	Ether extract	Nutritive ratio
In 100 lbs. of sunflower silage	21.4	1.24	10.13	0.37	9.8
In 100 lbs silage from well matured maize	26.3	1.1	15.00	0.70	15.1
In 100 lbs. silage from immature maize	21.0	1.0	11 40	0.40	12.3

No difficulty was experienced in getting cattle, sheep, or pigs to eat this silage. Some animals required a few days to become accustomed to it, while others ate readily the first time it was offered No objectionable flavours or odours could be detected in milk from cows fed thus.

Experiments were conducted from 1916-1918 to determine the relative feeding value of sunflower silage, clover hay and alfalfa hay. Results showed that 3.75 lb. of sunflower silage was equal to 1 lb. of choice aisike clover hay, when fed to cows receiving grain and a limited hay ration, and 2.83 lb. was equal to 1 lb. of alfalfa hay.

Chopped green sunflowers 30 to 40 % in bloom, were equal to chopped green corn in the roasting ear stage as a soiling crop for dairy cows. Experimental work up to the present, indicated that 30 % in bloom has a higher feeding value than silage made from plants less mature. The exact stage of growth that will give the highest quality of silage has not yet been determined; experiments are now in progress.

The silage was found a valuable substitute for part of the hay ration for breeding ewes and brood sows; 2.5 lb. of silage replacing 1 lb. of alfalfa hay in an entirely satisfactory manner.

The most practical method of harvesting sunflowers was found to be with the ordinary corn binder.

290 - **Flax Growing Experiments in Ireland, 1915-1919.** — *Department of Agriculture and Technical Instruction for Ireland, Journal,* vol. XX, No. 3, pp. 351-361, tables IX, Dublin, 1920.

I. — MANURIAL EXPERIMENTS. — A summary of the results obtained from the 4 series of experiments conducted by the Department during the years 1901-1915 inclusive, led to the following recommendations with regard to the advisable manurial applications to be made to the flax crops per statute acre. 1) On soils in good condition, 1-1 ½ cwt. muriate of potash or 4-5 cwt. kainit; 2) on poor or medium soils 1-1 ½ cwt.. muriate of potash or 4-5 cwt. kainit and ½ cwt. sulphate of ammonia. In the second case, the mixtures of potassic manures and sulphate of ammonia should be applied a short time prior to sowing the crop.

In 1917, trials were carried out at three centres to compare the results obtained from ground rock (containing about 5 % potash), with those from sulphate of potash. The first was applied at rates of 10 cwt, 1 ton and 5 tons per statute acre respectively both singly and in combination with lime. The results of these trials afforded no evidence that dressings of ground rock containing potash would serve as a substitute for dressings of the ordinary soluble potash manures.

In 1919, trials were carried out at 5 centres in which kelp, flue dust. muriate of potash, and sulphate of ammonia + muriate of potash were compared as top dressings for flax. Each of the dressings of potash manures used was equivalent in potash content to a dressing of 1 cwt. per statute acre of muriate of potash containing 50 % potash. The variety of seed used was Dutch, showing a germination % of 95. This was sown at the rate of 54 qts., per statute acre. Results showed that the brairds on the unmanured plots were severely affected with yellowing, but no trace of this disease was observed on any other plots dressed either with muriate of potash or kelp. Where flue dust was used there was a slight touch of yellowing.

After deducting the cost of manures, the various manurial dressings gave the following profits per statute acre:

	£	s	d
Muriate of potash + sulphate of ammonia	12	6	8
Muriate of potash	8	17	5
Kelp	8	4	0
Flue dust	1	15	7

II. — SEED TRIALS 1915-19. — In addition to Dutch, Russian and Irish, the varieties of seed of the fibre variety tested included British-East African, Canadian (Ontario), Canadian Western Fibre, Canadian Riga Child (Prov. Saskatchewan), Dutch (White Flowering), English, French, Scottish, and United States seed. The following seed varieties of flax were also tested; Minnesota 25, Canadian Common and Argentine; but none of these gave results that would warrant their being recommended for sowing for fibre purposes. Dutch seed was included in each set of trials each year for comparison purposes.

The variety tests were carried out on different classes of soils, and the results obtained, taken in conjunction with those of previous years, affords conclusive proof that no special variety is specially suitable for a particular class of soil. The relative merits of the various kinds of seed varied from year to year. The largest monetary return was obtained from English seed in 4 of the 5 years trials. Of the Dutch varieties, the white flowering var. gave substantially the largest in 2 of the years and slightly lower than the blue flowering var. in the 3rd. year. The white var. produced taller and slightly more branched flax, and was about 10 days later in ripening than blue. Neither the French nor the U. S. A. seed gave as good results as the Dutch.

Pure line seed trials were carried out in 1919. The Department's Pure lines Nos. 3 and 5 showed a striking uniformity of flax straw compared with that grown from any of the commercial varieties, and from these results it is clearly evident that the flax crop can be greatly improved through the propagation of pure line seed from single selected plants.

291 - **Susceptibility of Flax to Lime.** — LIECHTI, P. and TRUNINGER, E. (Mitteilung aus der schweizerischen agrikultur chemischen Anstalt, Bern), in the *Deutsch. Landw. Presse*, Year 47, No 9, p. 65, 1 fig. Berlin, 1920

Experiments carried out in triplicate at the Agricultural Station of Liebefeld, Berne, Switzerland with a sandy clay soil, poor in lime. The pots used each contained 5 kg. of soil, and were dressed before and during sowing with a nitro-phospho-potassic fertiliser. Shortly before sowing, one series of pots was limed at the rate of 20 to 80 quintals of CaO per hectare in the form of powdered, or coarse 2 mm. lumps carbonate of lime. The other series received no lime.

Seventeen days after the flax was sown, this operation being effected at the same date in the case of all the pots, the plants in the limed pots began to grow less vigorously, the seedlings suffering in proportion to the amount of lime present. The chlorosis previously recorded by FISCHER was not observed but, on the contrary, there was a larger accumulation of chlorophyll. The addition of lime had also the effect of retarding flowering, and the largest amount of lime prevented fructification and induced apical necrosis.

Yields obtained from each experiment with 3 pots.

CaO per ha. quintals	Dry matter of the crop Without Ca O gm.	 Fine lime gm.	 Coarse lime gm.	No. of seeds gathered
0	90.7	—	—	285
20	—	56 1	—	5
80	—	30.8	—	0
20	—	—	87.3	289
80	—	—	79.5	80

The authors believe that the specific action of a dressing which, like lime, has an alkaline physiological reaction, has something to do with this phenomenon : this would agree with the results obtained by KLEBERGER, FISCHER, KUHNERT and HILMER. According to FISCHER, the addition of potassic salts may neutralise the injurious effect of the lime. The authors explain this beneficial effect of potassic fertilisers, as being due to their acid physiological reaction ; they explain the stimulating effect of plaster (gypsum) in the same manner, but state that they are unable to give the ultimate physiological reasons of the curious behaviour of the flax (1).

292 - **" Silver Wattle" Gum, Obtained from *Acacia Rivalis*.** — ANDREW, H. W. in *The Journal of the Department of Agriculture of South Australia*, Vol. XXIV, No. 3, pp. 207-209 Adelaide, October 1920

The author observes that although this acacia has been known commercially for a good number of years, no previous record in Australian literature is to be found as to the distribution or botanical name of the tree from which the gum is derived. On examination of the tree indicated as giving the gum, the author identified it as *Acacia rivalis*, which has a distinct affinity to *A. leprosa*, Sieb. var. *tenuifolia* Benth, in the flowers and bracts, and with the narrow forms of *A. stricta*, Willd. in the phyllodes and general appearance, but the flowers and pods are totally different, the latter a good deal like those of *A. calamifolia*.

Production of gum varies very much according to the climatic conditions of the gumming season, which usually begins in January; 4-14 tons are said to be produced annually in the Blinman district of S. Australia. Examination showed that the gum distinctly resembles in appearance gum arabic obtained from *Acacia senegal*, varying from light yellow to a cherry red, frosted on the surface. Another local trade name for the gum is " first light grade gum. " Supplies come chiefly from the district mentioned, but the author suggests that a definite mapping out of the region covered by this tree which appears to be peculiar to this part of Australia, might be undertaken with advantage.

293 - **American Storax Production: Result of Different Methods of Tapping Red Gum Trees (*Liquidambar styraciflua* L.).** — GERRY, E (Microscopist, Forest Products, Laboratory, Madison, Wis.), in *Journal of Forestry*, Vol XIX, No. 1, pp. 15-24, figs. 4. Washington, D C., January 1921.

Experiments were carried out in Louisiana to compare three different methods of obtaining gum from *Liquidambar styraciflua* L., a gum which should prove equally satisfactory for commercial purposes as that obtained from *L. orientalis* Mill. In May, 1919 ten trees were " deadened " or girdled by removing a strip of bark several inches wide from the entire circumference of the tree, 20 were tapped perpendicularly, and 20 were tapped horizontally.

The largest yield of storax after 8 tappings was obtained by horizontal tapping, and was secured during the hot August weather. The following shows the varying amounts obtained by the different methods :

	Perpendicular taps	Horizontal taps	Deadened
	grams.	grams.	grams.
Total storax	809.5	1456.8	428.5
Average per tree	40.5	72.8	42.8

---

(1) The susceptibility of flax and other plants to lime has also been shown by recent experiments made in America. Cf. *R* Jan. 1919, No. 10. (*Ed.*)

Specimens were selected for microscopic study in the Forest Products Laboratory, and represented examples of the effects produced by these methods of tapping. The results agreed with those derived from field experiments. The gum and gum ducts apparently do not form in sufficient abundance, if the tree is " deadened ", to produce a high yield. The same reason holds good with the perpendicular tapping. The horizontal method stimulated the formation of wood and gum ducts, and promised a means of easily obtaining sustained yields, by freshening the chipping once or more each year, removing a $^1/_4$ to $\frac{1}{2}$ inch chip, where the production of gum is characteristically more abundant. The cut should be only deep enough to expose completely the surface of the last formed wood, and it is suggested that about $^1/_3$ of the circumference should be covered with the uncut bark. Necessary precautions must be taken to check the entrance of decay through exposed wood.

The author considers that according to the information now at hand, and taking everything into account, cutting the wounds on the gum trees early, say in February or March, would be an experiment well worth trying.

294 – **The Camphor Laurel and its Products.** — PERROT E. and Mme GATIN V., in the *Ministère du Commerce et de l'Industrie, Travaux de l'Office National des Matières premières végétales pour la Droguerie, la Pharmacie, la Distillerie et la Parfumerie*, Notice No 4, pp. 60 + 9 figs., bibliography of 41 works. Paris, July 1920.

In the first chapter the authors deal with:

(*A*) Characteristics and utilisation of the products of the camphor laurel (*Laurus Camphora L.* = *Cinnamomum Camphora.* Nees and Eberm. = *Camphora officinalis* Nees) : — Camphor, crude oil of camphor, white oil of camphor, red and black oil of camphor, safrol and light heavy and blue oils of camphor.

(*B*) Production of and trade in camphor and oil of camphor (1). In the second chapter the authors deal with the geographical distribution of câmphor and state that *Cinnamomum Camphora* lives to be 2000 years old and attains enormous girth ; the trunks of some specimens in China and Japan were 5-7 metres in diameter. In Japan, Formosa, and Tonkin two varieties of camphor tree are known, one with green and the other with red branches. Some authors describe them as different species but EBERHARDT found green and red branches on the same tree ; some yield camphor and others camphor oil without there being any relation to their colour. EBERHARDT considers that the nature of the product is related to the histological differentiation of the tissues; when the oil is dominant, it is due to insufficient lignification.

The species which most nearly approach *C. Camphora* are : *C. Parthenoxylon* Meissn, *C. Balansae* Lecomte, *C. ilicoides* A. Chev. and *C. Simondii* Lecomte. The leaves of these different species are very similar, but when rubbed they give off different perfumes. The inflorescences and fruits also possess many common characterics. Like the camphor tree these species, produce, in October and November, seeds, which germinate easily. In Indo-China, there are *C Camphora* and another *Cinnamomum* which has been identified by DUBARD as *C. cecidodaphnae* var. *canifora,* also a camphoriferous species.

---

(1) See *R.*, May, 1920. No. 528. (*Ed.*)

The camphor tree prospers in all countries where the rainy season is well marked, on the banks of rivers, and on mountain slopes up to an altitude of 2000 metres. It is not very exacting as regards soil, but prefers a sandy-clay soil that is light and well drained.

In chapter III. The authors deal with:

1) The camphor industry (exploitation of the camphor tree in Japan and China, distillation, refining and conservation of the refined camphor).

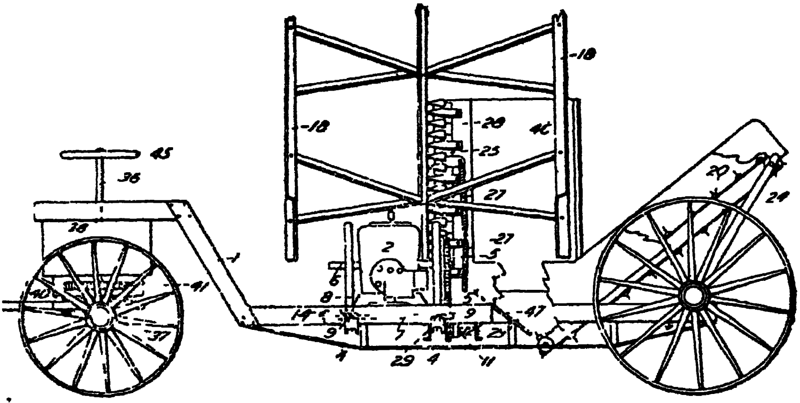

FIG 1 — Side view of a camphor harvester.

2) Experiments on the distillation of camphor leaves. They quote the work of HOOD & TRUE, GIGLIOLI, TARBOURIECH, EATON, KOZLOV, etc. All those who have dealt with camphor agree that the leaves yield enough camphor (about 1 %) to make the cultivation of the camphor tree on a large scale profitable, by yielding camphor more cheaply than the Japanese product.

Chapter IV deals with the cultivation of the camphor tree:

1) Experiments on the introduction and cultivation of the trees in different countries.

2) Choice and preparation of the soil (cultivation is possible in all soils, except in low-lying soils that are inundated during part of the year). The best soils are rich and well drained; the soil must be ploughed deeply before planting the seedlings.

3) and (4) Propagation by seed, slips and layers.

5) Final plantation.

6) Leaf crop and yield in crude camphor.

7) Machine for harvesting the leaves and branches.
8) Yield in leaves and crude camphor.
9) Parasites of the camphor tree.

The harvester mentioned above is an American machine, drawn by mules or a motor, and the authors give the following description of it:

1) A truck whose iron platform supports the cutter.
2) An internal-combustion engine placed on the platform.
3) A cutting device comprising a cutting blade carrying the reaping hooks, and a winch, the whole supported by springs so as to diminish vibration.

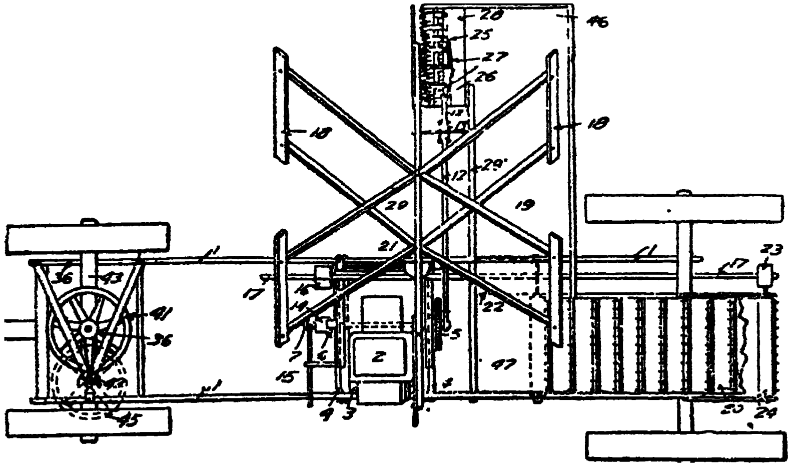

Fig. 2. — Elevation of a camphor harvester.

4) A cutting blade held rigidly at the proper cutting angle, furnished with knives or reaping hooks and connected to the engine and to the winch.

5) A reel to remove the twigs and leaves that fall between the knives.

6) A platform for collecting the crop in a sack which can be fastened behind the truck. This machine is not difficult to handle. Three men are necessary when mules are used, but only two men when a tractor is used.

The angle and cutting line being fixed the machine functions as follows;

The engine is started which starts the cutters moving, and the clutch operating the reel and platform is engaged.

The driver and the operator direct the machine according to the line to be cut, using the eye as a guide. The reel moving at a certain speed engages the young shoots between the cutters and at the same time the force of the blow given by the reel throws the parts of the trees cut by the cutters on to a platform placed at the base of the knife beam. The leaves and small branches are gathered by the moving platform whence they are carried into a bag.

A second platform, operating at right angles to the first, gathers the cut materials and places them in a receptacle for transport to the distillery.

Chapter V deals with the chemical composition of camphor and oil of camphor, the percentage of camphor in the oil, and substitutes for camphor.

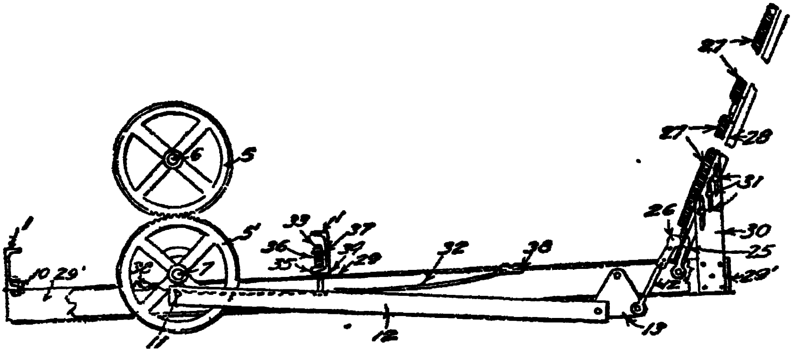

FIG. 3. — Transmission of power from engine to cutter blades.

In chapter VI the authors summarise the most important work that has been done on the formation and distribution of the camphor-secreting cells in the plant. Camphor is an oxidation product of an oil localised in special secreting cells distributed throughout the tree. The root possesses them especially in the cortical parenchyma; in the stem, they are found in the bark, the medulla, the woody parenchyma and the medullary rays. The autumn wood is richer than the spring wood. In the leaves these cells are located in the palisade and lacunose tissue. The petioles are extremely rich in the secretive cells, which are also found in the bud scales. In chapter VII, the authors study synthetic camphor and in the VIIIth and last chapter they summarise the history of the drug and deal with the therapeutics of camphor.

295 – **The Question of the Distance between Sugar Cane Rows.** — ROSENFELD A. H., in *The International Sugar Journal*, Vol XXII, Nos. 262-263, pp. 558-565, and 629-635, tables XVII. London, Oct.-Nov. 1920.

Report of the various investigations made in connection with the spacing of sugar cane plants with a view to allowing each plant to obtain its maximum development. The experiments reported were conducted in Louisiana, U. S. A., Hawai, Cuba, Guadeloupe, Java and at Tucuman, in the Argentine. Rows were spaced at varying distances of from 3-8 ft, and records kept of the average yield of canes per hectare, of the quantity and value of the sugar obtained, and of the comparative financial advantages of each method employed.

From this extensive survey of experiments made all over the world, the author states that it may be safely concluded that sugar should be planted in rows as close together as is consistent with proper cultivation with modern machinery, this distance appearing to be about 5 ft. for the thicker types of cane such as Cheribon, Lahaina, B 208 etc., and from 5 ½ to 6 ft. for the more abundantly suckering types such as the Java canes, the Uba, and the Japanese bamboo type, etc.

296 - **Studies in Mustard Seed and Substitutes. — I. Chinese Colza *(Brassica Campestris Chinoleifera.* Viehoever)** (1). — VIEHOEVER A., CLEVENGER J. F., and EWING, C. O. (Bureau of Chemistry, United States Department of Agriculture), in *Journal of Agricultural Research*. Vol. XX, No. 2, pp. 117-139, Pl 10, tables 6, bibliogr. of 52 works. Washington, D C, Oct 15, 1920.

Shortly after the outbreak of war, mustard seed which previously could be obtained from European countries was no longer available, and it was necessary to seek other sources of supply, but in some cases the seed offered as mustard was quite different not only in quality, but also in general appearance and condimental character. Material imported as rape seed and sold as mustard seed was identified as Chinese colza, *Brassica campestris chinoleifera* Vichoever. n. var.

Studies were undertaken to determine the macroscopic and microscopic characteristics of the seeds, as well as the chemical composition and certain physiological characteristics of the volatile oil. Plants were also grown to maturity, and the characteristics at the different stages of growth were determined. These experiments were correlated with data in literature dealing with the subject, and as a result the seeds were identified as those of Chinese colza. The authors add that this was previously classified as *Brassica campestris chinensis oleifera*, n. f., but was changed to its present name to avoid the use of a polynomial. The volatile oil obtained was identified as crotonyl isothiocyanate, which is not a suitable substitute for mustard oil, in respect to condimental, bactericidal, or medicinal value. The fixed oil proved to be of the general composition of the rape oils, and the quantity of the oil present, amounting to more than 40 %, characterised the seed as a very valuable oil seed.

On the basis of the general composition of the seed and the character of the volatile oil, it is suggested that the pressed oil cake may well be used as a stock feed. The leaves are succulent and should be valuable as a vegetable food. The plants, which are very vigorous and apparently hardy, seem to offer possibilities as a forage crop. Experiments along this line have been undertaken in co-operation with the Bureau of Plant Industry.

297 - **Tobacco Growing in Western Australia: — Notes for Intending Planters.** — *Department of Agriculture, Fruit Industries Branch, Bulletin* No. 74, pp 3-8. Perth, 1920.

The Tobacco Expert of the Department of Agriculture of Victoria, from whom the information contained in these notes has been obtained, states that sandy or shaly soil is best suited for the production of bright tobacco. The less clay, the better the quality of the leaf Heavy soils containing a proportion of clay, are suitable for the production of heavy, dark types which return a lower price but give big yields per acre. Soils which become waterlogged are unsuitable and good drainage is essential.

Moderate rain with warm weather is the best general condition. Dry weather during the ripening stages preserves the products required for aroma in tobacco, and dews in autumn also have a good effect on the leaf. Water should never be applied after the plants are topped, as it is then liable to affect them detrimentally during curing.

Varieties recommended are as follows: —

On light sandy soil, for cigarette leaf: — Little Orinoco, Yellow Pryor, Bonanza, Hyco and Granville Yellow.

On rich river flats — for pipe tobacco: — Medley Pryor, Blue Pryor and Lax.

On red chocolate soil for pipe tobacco. — Hestor and Conqueror.

On soil from 70 % to 90 % sand, — for cigar tobacco. — Connecticut seed leaf, Havana and Comstock. (Either regular rainfall or irrigation is necessary to grow the plants when the sand percentage is high, and the leaf texture very fine).

On red chocolate loam or strong sandy loam, — for cigar tobacco, — Vuelta de Abajo, Comstock and Pennsylvania.

One ounce of seed will provide sufficient plant for from 7-10 acres of heavy tobacco; and 2-4 acres of cigar tobacco, the latter being planted closer in the field to obtain a better texture; 1 oz. will be required to plant a bed having an area of 50 sq. yds. It is advisable before sowing to mix with about 20 times its own bulk of sifted wood ashes, dry sand or bone meal.

Conservation of moisture is an important factor during the growth of plants, until they become too large to admit of being worked between.

The following formula for fertilising poor soil per acre is given: — 300 lb. of lime, 200 lb. sulphate of potash (muriate of potash not to be used), 100 lb. of bonedust, and 1½ cwt. red blood.; the lime to be applied in the autumn, and the rest to be spread broadcast just before planting, and harrowed in.

It is advised to avoid cutting directly after rain and in the early morning.

After thorough curing, stripping and classification, processes all described in detail, and after the tobacco is again hung in the shed, it should be kept in sweet condition until the spring by the use of fires or ventilation, and the shed kept darkened. The next procedure, namely bulking, is advised when the midrib will crack $^2/_3$ of the way up the leaf, and when the leaves on being squeezed together in the hand, will open of their own accord when released. The fermentation of cigar leaf is a much more scientific process than that for heavier types of tobacco, and new growers are not advised to attempt it, but rather, to sell the leaf to the manufacturers as soon as the curing in the shed is completed.

The maximum amount of moisture required for safety before packing is from 10 to 12 %. The usual custom in Victoria is to pack the tobacco for market in bales, containing from 150 to 250 lb., made of hessian.

298 - **Grafting in India.** — I. PRAYAG, S. H., The Influence of Stock and Scion and their Relation to one another, in *The Agricultural Journal of India*, Vol. XV, Pt V, pp. 533-542, figs. 2. Calcutta and London, Sept 1920 — II. BURNS, W. and JOSHI, P. G., "Top-Working" of Indian Fruit-Trees, *Ibidem*, pp. 516-520, pl 3, Sept 1920.

I. — The author states that although much has been written regarding this subject, the fruits dealt with are unsuitable to Western India In this article it was intended to put together all the available material dealing with some important fruit trees and other plants with a view to inviting suggestions and criticism.

In order to ascertain the best stock on which to bud any variety of orange, pumelo, lemon etc., trials were made in the Ganeshkind Botanical Gardens since 1909 in which all the available varieties of *Citrus* in the Deccan were budded on the following stocks:— "Mahalunga" (*Citrus medica*,proper) "Jamberi" (*Citrus medica* var.), orange and "Reshmi" orange (*Citrus Aurantium*). The following results were obtained.— Scions of hardier varieties with thick bark from large round stems did well on *Citrus medica* but the "Jamberi" (*C. medica* var.), is preferable as a stock plant. The bark is mucilaginous and separates more easily from the wood below than that of Mahalunga and the plants showed a decidedly superior quality both in height and appearance to those on other stocks. It is well known that certain stocks have a very pronounced effect upon the habit of growth of the scion. *e. g. Crescentia alata* grafted on *C. Cujete* gives plants very dwarf in size. A similar result is obtained with apples on Paradise or dwarf stock (*Pyrus praecox*).

Experiments made by the author with grafts of " neem " (*Azadirachta indica*) on " bakan " (*Melia Azedarach*) showed that the formation of a big knotty excrescence takes place at the grafting juncture, owing to the different rate of growth of the two plants and the growth is thereby considerably checked. This check in the flow of sap due to the difference in the period of activity of stock and scion with consequent disaster was also demonstrated in experiments with *Ficus carica* on *F. glomerata*, and *Ipomoea Horsfalliae* on *I. carnea*.

The scion has a preponderating influence in producing its own quality of fruit. That the position of the mature scion at the end of a branch in a big tree does influence the flowering has been proved by experiments in various districts with the mango tree. Results are however, still inconclusive, but the question has an important practical bearing, as, if early flowering is induced on young transferred branches, considerable saving of time would be assured, and such plants as hybrid and polyembryonic mangoes, seedless guavas. etc. would be forced to reveal their characters at an early date.

The insertion of more than one variety on the branches of a single stock has been found undesirable.

In order to determine the influence of stocks and scions of different genera but belonging to the same natural order, the author conducted experiments with the N. O. Anacardiaceae. Grafting between different genera in this case met with failure.

II. — The author believes that the experiments here mentioned are the first of their kind in India, although the method of " top working " (renovation of the whole of the top of the tree by inserting scions in the existing branches and arranging that these scions grow while the old branches of the tree are removed), has been employed elsewhere.

Two obvious advantages of this methods were: 1) The top of the tree is not entirely removed which is an unavoidable necessity with crown-grafting;— 2) The scion is not taken away from its original water connections until the new are fully established, being attached to its own original plant until union occurs.

The following is an example of experimental trials:— A country mango tree in Bassein, near Bombay, of unknown age was heavily cut back on March 6, 1912. Many new shoots sprang up from the stumps and on these were grafted scions of good varieties on May 22, by inarching from plants in small pots tied to the tree in various places. On November 1, further grafting was done from the now established scions on to new shoots of the stock. Out of a total of 40 scions, 3 flowered in June 1914. It was apparent that by top working, flowers can be got 14 to 20 months after operation. The pot plants from which these scions were taken, did not flower. The first real crop was obtained from the tree in June 1916. There were 38 fruits of 4 varieties and these all retained their own characters although grafted on the same stock plant.

Top-working was also done with considerable success on wild trees and can be applied advantageously for the conversion of useless wild trees into good bearing trees. *Mimusops hexandra* can be top worked with scions of *Achras sapota* (the sapodilla plum or " chiku ").

Another application of top-working is in the starting of new mango plantations. The author advises the planting of the seeds of the stock plants in the field where the tree is wanted and afterwards to graft on to the stock when sufficiently grown.

Similar results with the so-called seedling inarch method of propagation have been got in America (*U. S. Bureau of Plant Industry, Bulletin* 202) with mango, mangosteen (*Garcinia mangostana*) and litchi (*Litchi chinensis*) etc.

299 - **The Banana Industry of the Honduras Republic.** — *The Board of Trade Journal*, Vol. CIII, No. 1194, p. 482 London, 1919.

Honduras, of all Central American countries, probably offers the best prospects for the cultivation of bananas, and it is possibly the only remaining country possessing reserves of land suitable for the industry. For the last twenty years the cultivation of this fruit has been actively followed all along the Atlantic coast, from the Mexican Gulf to the mouth of the Magdalena.

High winds and floods have caused considerable destruction, and a disease — the origin of which has not yet been ascertained — has done considerable damage to the estates. As a result of this disease plantations in Colombia, Costa Rica and Jamaica are practically on the road to ruin, none of the known remedies having succeeded in rooting out the evil.

Honduras is one of the oldest banana-producing countries, some plantations, twenty years of age, still producing fruit in abundance The banana lands on the coast are formed by layers of soil deposited by the watercourses, which during the yearly period of floods inundate the surrounding country, and thus act as a fertiliser. Truly alluvial soil exists in the valleys of the Chamelecon and Ullua rivers, which owing to their length, volume of water, and swiftness of current, cause at the season of floods, a more extensive inundation and retention of water, leaving deposits of rich soil.

Although Honduras may not possess a population in comparison with its area, there is no shortage of labour. The inhabitants of the interior have been attracted by the high wages offered by the American companies, and, in addition to labour already available, it is customary to send recruiting agents into the interior. Women and children are not in the habit of working on the coast plantations

As a result of war conditions, combined with the floods and disease, the enormous requirements of the American market have not yet been met, and so long as a company is able to supply its own means of maritime transport, there is little doubt that Honduras offers a very favourable field for enterprise.

300 - **Poultry-Keeping in Fruit Plantations.** — See No. 325 of this *Review*

301 - **Vine Growing in the State of Rio Grande do Sul, Brazil.** — Esquier, L. in *Brasil agricola*, Vol V, No 10, pp. 301-302. Rio Janeiro October, 1920.

The soil of Rio Grande do Sul is excellent for vine-growing and there are already 30 000 hectares under vines in the State, 900 000 hectolitres of wine being produced yearly. The vineyards are mostly situated in the mountain districts, in the neighbourhood of Caxias, Garibaldi, Bento Gonçalves, Alfredo Chaves, Antonio Prado and Guaporé, where the soil is a strong, stiff, sandy clay.

The climate resembles that of Southern Europe, mean temperature in spring and autumn being from 16°C to 17°C, whilst it is 22°C in summer. The winter temperature is sufficiently low to allow vegetation to rest. There are, however, two serious drawbacks, viz., frequent spring frosts, and the heavy rains during the growing period of the vine. These encourage the spread of fungoid diseases (anthracnosis, mildew) to an unusual extent

According to data collected by the Caxias meteorological Station, there were 146 wet days in 1914, the total rainfall during that period being 2914 mm.; half of this amount fell during the vegetative period of the vine.

In Rio Grande do Sul, American vines, varieties or hybrids of *Vitis Labrusca* or of *Vitis aestivalis* (Isabella, Clinton, and Herbemont) are chiefly grown: they produce grapes of mediocre quality. A few European varieties are, however, also cultivated.

The vines are usually grown on trellises; pruning is done without any method, and the soil is never ploughed; therefore there is much room for improvement, As a rule, the grapes are made into wine by the cultivator, whose methods and apparatus are alike primitive.

At Caxias, there is a well established Co-operative Wine Society, which exported, during the first half of 1920, some 5000 hectolitres of wine. Another similar society exists at Bento Gonçalves.

Phylloxera has been reported from all the territory of the municipality of Garibaldi, and is slowly spreading. M. ESQUIER therefore advises the introduction of more resistant stocks than those at present cultivated. He suggests as varieties suitable to the climate, Riparia Grande Glabre, Riparia Gloire de Montpellier, and hybrids of Riparia × Rupestris Nos. 3306, 3307, 3308 and 3309. As grafting varieties he advises Malbec, Pinot, Carignan, Cinsault, Grand Noir, Aramon, Clairette, and white Urgni. M. ESQUIER also advocates the trial of the hybrid direct bearers Couderc 7120, Seibel 1000 and Gaillard 157.

In conclusion he advises the establishment at Caxias, of a viticultural and Oenological Experiment Station.

302 – **Vines of Trentino: the Teroldigo and Negrara Varieties.** — DALMASSO, C., in *L'Italia agricola*, Year LVIII, No. 1, pp 5-7, 1 fig, 1 coloured plate, No 2, pp. 49-50. Piacenza, January 15–February 15, 1921.

I. THE TEROLDIGO VINE. — The author draws attention to this vine which is one of the most important in the Trentino, though it is not to be found in any of the Italian or French Ampelographies. ACERBI alone (*Delle viti italiane*, Milano, Silvestri, 1825) mentions, in the Catalogue of Italian and foreign vines cultivated in his vineyard near Castelgoffredo, among the vines from the neighbourhood of Trent a " Teroldega maggiore " and a " Teroldega minore " This very laconic description was copied by ROVASENDA (*Saggio di un Ampelografia universale*, Turin, S. Marino 1879) and, later, by CAVAZZZA (*Viticoltura*, " Nuova Enciclopedia agraria italiana ", Turin, U. T. E. T., 1914), and by VIALA and VERMOREL (Ampelographie, Masson, 1909).

On the other hand, a succinct description has been given by German students of the vine, beginning with GOETHE (*Ampelographisches Worterbuch*, Vienna, Faesy and Frick, 1876; *Handbuch der Ampelographie*, Graz, Leykam, 1878), and later, by BABO and MACH (*Handbuch des Weinbaues und der Kellerwirtschaft*, Berlin, P. Parey, 1909).

For this reason, the author thinks it advisable to give further details concerning this vine.

Synonymy. — It has no true synonyms, although its name has been more or less altered into "teroldico", "teroldego" and "teroldega". Sometimes it is called "trellinger" in the Upper-Adige, which, according to Goethe, is wrong, this being the name of a quite different vine ("Frankenthal" or "Schiavone"). From Acerbis' catalogue, it might be supposed that there were two varieties of "teroldigo"; the author has, however, never found more than one.

Localities where it is cultivated. — The original home of this vine is not known for certain. At the present time, it is grown almost exclusively in the plain of Mezolombardo (Valley of the Adige), which includes the Communes of Mezolombardo, Mezocorona, S. Michele and Grumo.

Ampelographical Description. — Vigorous grower, although inferior in this respect to other Trentino vines.

Roots rather shallow.

Canes long and slender, reddish-brown in colour, slightly tinged with violet at the nodes, internodes average, cortex striated. Buds prominent.

Buds yellowish-green, covered with thick whitish down giving them a characteristic appearance in spring. Buds early.

Leaves of average size, tri-quinque lobed with shallow lateral groove, and petiolar groove nearly closed; upper surface dark-green, opaque; lower surface, light, thickly covered with hairs; mucronate, teeth fine, veins yellowish. Petiole of average length, violet-pink, tomentose. The lamina turns red at the time of vintage. Leaf-fall somewhat early.

Bunches of average size, pyramidal in shape, rarely cylindrical (only where two bunches grow on adjacent nodes), generally winged (with one or two wings), somewhat compact: Peduncle rather long and strong; pedicels short and green; graft callus little noticeable; brush red; Grapes average sized, slightly ovoid, blackish-blue, with much bloom; skin very resistant, rich in colouring-matter and tannin; pulp juicy, flavour sweet, clean. Pips of average size, 2 or 3 in number at most.

Maturation at the 3rd period, but the grapes can remain fairly long on the vine without rotting.

Practical Information Respecting this Vine. — The "teroldigo" likes light, permeable, alluvial soils, and does not ripen well on heavy soils. When grown on fertile soil, its grapes are less characteristic.

Hence, the best soils are those of the old bed of the Noce, near the point where it joins the Adige.

As the base shoots do not bear grapes, the "teroldigo" vine must be pruned long. It is very well suited to the typical "pergola" system (trellises forming an arbour) of Trentino. Grown thus, it bears a heavy crop, more than 100 and sometimes as much as 200 hectolitres of pressed grapes.

The "teroldigo" is rather susceptible to mildew and oidium; it is still more liable to anthracnosis, and the attacks of *Tetranychus telarius* (very common in Trentino). This variety has much affinity with American vines and grafts well on most of them.

Practical Information Respecting the Wine. — The wine made from the grapes of the "teroldigo" is one of the favourite vintages of Trentino. When grown on good positions the grapes yield a must with a high sugar content, with, however, decided acidity (a rare character in Trentino vines). The 30 years' average sugar content of must made from grapes grown in the vineyards of the San Michele Agricultural Station was 19.2 % (BABO glucometer), the maximum being 23.4 %, the average acidity 7 per 1000, and the maximum 10.9 per 1000.

The wine made from the finest "teroldigo" grapes is excellent, full-bodied, rich in colouring matter and tannin, and possesses a special, very agreeable bouquet. When not allowed to ferment too long on the pomace, it can be used at once and, if properly aged, makes a good wine for bottling. Usually however, "teroldigo" is in request as a half-blending wine for transforming the local white wines into red table wines.

During the years preceding the war, "teroldigo" was also much appreciated in Germany and Switzerland, whither it was often exported in the condition of pressed grapes.

II. THE "NEGRARA" VARIETY. — SYNONYMY: In that part of Venetian Trentino where German is spoken, this vine goes by the names of "Edelschwarze" and "Salzen". It is chiefly known by the latter appellation at Meran.

AREA CULTIVATED. — This variety is much grown in Venetian Trentino, and especially in the Trentino properly so-called, viz., at Rovereto, Calliano, in the neighbourhood of Trent, at Lavis and at San Michele. Subsequently it also spread to the Upper-Adige and the Ueberetsch at Meran.

AMPELOGRAPHICAL DESCRIPTION. — *Canes* of average thickness, long, brownish-yellow in colour, with violet-red shades that are lighter in winter, finely striated; nodes somewhat swollen, internodes average or above the average; buds very prominent.

Buds green, glabrous, glossy, a little brown, but only at the extremities; covered with fine hairs. Budding average.

Leaves of average size, trilobate (rarely five lobed) with deep upper sinus which is rounded and closed, or nearly so. Sinus of petiole open, forming a U., upper surface dark-green, vesiculate; lower surface with slight silky down; large irregular teeth; veins very prominent on lower surface; has a slight violet tinge. Petiole small, short, pink. Leaf-fall average.

Bunches large or very large, rather long, pyramidal, winged (often with 4 wings) a little compact. Peduncle long and strong, semi-ligneous; pedicels of average length, green, a little verrucose, graft callus large, verrucose, violet; brush pink.

Grapes above average size or large, round (sometimes slightly flattened); colour very dark blue, very much covered with bloom, skin often resistant, pulp succulent; flavour clean, sweet, agreeable.

Pips of characteristic shape, beak long and inflated (much compressed at the chalaza); generally 2, rarely 3 in number

Maturation at the 3rd period, late.

PRACTICAL INFORMATION RESPECTING THIS VINE. — It requires light, warm soil, and as it grows best when exposed to the sun, is well suited to hills or slopes, but not to the plain. It is a vigorous grower, needing much pruning, and is therefore well adapted to the Trentino " pergole ".

Yield rather inconstant; when grown on its own roots, it fruits late, but is earlier if grafted. The yield also varies according to the soil, being less heavy on stony than on heavy soils; the quality, however, varies in an inverse manner. The average 20 years' production of the vineyards belonging to the San Michele Agricultural Institute was 55 hectolitres per hectare, with a maximum of 103 hectolitres.

This vine suffers much from oidium and *Tetranychus telarius* whereas it is very resistant to anthracnosis and cold. Does well on the chief stocks, although the grafts appear rather weakly in the nursery.

PRACTICAL INFORMATION RESPECTING THE WINE. — If grown in a good situation, the Negrara grapes produce a strong, rather highly-coloured wine with characteristic bouquet when bottled As a rule, the wine is of the ordinary table variety. At the Institute of San Michele, the average sugar content for 30 years (according to the BABO glucometer) was 17.3 %; sometimes it rose to 21 %, whilst the average acidity was 7 °/₀. Negrara grapes are often pressed with those of the Rossara and Schiave varieties, in order to obtain a good ordinary table wine.

303 - **Eucalypts Resistant to Heat and Drought, Observations made in Southern California.** — MUNNS, E. N. (Forest Examiner U. S. Forest Service), in *Journal of Forestry*, Vol. XIX, No. 1, pp. 25-33. tables 6, Washington, D. C., January 1921.

In June, 1917, at different stations in Southern California the mean temperatures averaged 3 to 4° above the monthly mean, the maximums were 10 to 15° above the normal and ranged from 100 to 124°F. The effect of these trying conditions upon all plant life was very noticeable, and the drought affected the eucalypts also to a marked extent, especially the foliage. The character of the soil indicated by the moisture equivalent, influenced the amount of damage to a striking degree. On sandy soils, the damage was far greater that on any other kind of soil. The author indicates for a number of places where plantations were inspected, the species, nature of soil, and the character of the injury. The following table shows the percentage of trees injured, based on the general soil types.

Soil type	No of trees basis	Trees killed	Percentage of trees insured				
			All leaves killed	Partial loss of foliage			
				over 50 %	10 to 50 %	Under 10 %	No damage
Sand	7 288	18	21	16	19	28	16
Sandy loam	5 116	—	—	1	8	30	61
Loam	1 982		—	—	—	18	82
Clay loam	2 109	1	6	11	37	40	6
Clay	334	—	13	11	29	31	16

From general observation, eucalypts can apparently withstand drought if planted in loamy soils or where the trees are able to reach the permanent ground water. Of the species noted, taking into account the conditions to which they were subjected, the age of the trees, and their treatment, 2 species *E rostrata* and *E. tereticornis* appear to be the best for planting in regions of high temperature and high evaporation These make the most rapid growth and under the severest conditions, withstanding both low and high temperatures, and are more adaptable than other important species to wide ranges of soil and site conditions

304 - **Experiments on the Value of Common Rock Salt and Sulphur for Killing Live Stumps of Trees.** — RUDOLFS, W, in *Soil Science*, Vol IX, No. 3, pp 181-186 pl 2. Baltimore, M. D, March 1920.

The clearing of land in New Jersey, where great tracts of valuable land are covered with pine and oak wods is commonly accomplished both by the " suckering " method and with the help of goats To find a means whereby the clearing would be less costly, and whereby the land could be improved, possibly after 1 or 2 years, was the object of the experiments here reported. These were carried out under somewhat different climatic and soil conditions, the latter including swampy, and dry sandy soils, and a sandy loam

According to analyses made, the common rock salt employed, contained 97 to 98 % sodium chloride, a little magnesium chloride, and a few impurities. Results showed that this when applied to oak stumps which have been allowed to grow for several years, does not do much harm when applications of from 2 to 2 ½ tons per acre are given When applied in amounts of ½ to 1 ton per acre, these shrubs are stimulated, the salt acting as a fertiliser. In cases where trees have been cut in winter time and the brush burned on the premises the stumps are much retarded in their growth, by applications of salt at the rate of ½ to 1 ½ tons per acre Applications of 2 to 3 tons per acre will kill stumps of white and black oak, or cause eventual death The resistance of the stumps generally, after treatment with salt, was apparently in the order of oak, cherry, chestnut, dogwood, birch and maple The last was affected very easily

The best time to make applications is apparently the spring, just before the leaves appear, and when the sap stream is able to carry the chlorine to the buds and young leaves

Application of sulphur on high or low oak brush as a means of clearing land for agricultural purposes, was of no value Instead, sulphur seemed to have a stimulating effect upon the growth of live tree stumps

305 - **The Accuracy of the Different Cubing Methods Applied Comparatively to the Beech-tree in Italy.** — FERRARI, E, in *Le Stazioni Sperimentali agrarie italiane*, Vol LIII, Part 12, pp 505-514 Modena, 1920.

In order to determine the mass of the wood of 17 standing beech trees in the inalienable forest of Camaldoli, the author applied the following 7 methods, set forth in order of their accuracy

(1) By 1 metre sections (control) error $^0_0$	0.000 cubic metres
(2) With specimen trees classed diametrically, + error	2.73
(3) With the average coefficient, + error	3.02
(4) With diameter at $^1/_4$ and $^3/_4$ height, — error	3.94
(5) With specimen trees (URICH method), + error	5.17
(6) With average trees, — error	7.75
(7) With diameter ½ height, — error	11.78

The author thinks that the best method for deciduous woods is the mixed method, that is to say, the volume of stem that can be used is determined on the basis of the diameter half-way up obtained by the Camaldoli hypsodendrometer, and to estimate by the eye the rest of the wood which is to be used for making charcoal, tree by tree. No other method is successful because the amount of workable wood varies from tree to tree.

This is why it is necessary, for irregular, deciduous woods, to determine first of all the mass of the stem (up to the tip) by means of the abovementioned method, making use of the hypsodendrometer. It is necessary to increase the volume thus obtained by employing a fixed percentage (in the case in question 12 %) and then to judge by eye the percentages, tree by tree, comparing them with the volume of the stock utilisable for timber.

As an alternative it is possible to gauge the volume of utilisable wood in the trunk on the basis of the diameter half-way up with the hypsodendrometer, and then fix by eye *a priori*, in each tree the volume of trunk remaining and that of the branches to be used for charcoal. In order to make sure, the wood when cut should be measured per cubic metre when piled for making charcoal.

LIVESTOCK AND BREEDING

306 - **The Frequency of Latent Forms of Bovine Piroplasmosis in Morocco.** — BALOZET L., in the *Bulletin de la Société de Pathologie exotique*, Vol XIII, No. 9, pp. 733-734, 2 figs Paris, November 10, 1920.

The Moroccan form of bovine tuberculosis studied by VELU (*Bulletin de la Société de Pathologie exotique*, No. 8, 1915) is very common in the well watered regions at the foot of the Middle Atlas, where vegetation is luxuriant, and Ixodineae are especially numerous. The disease rarely attacks the cattle of those districts, and any cases that occur are of a benign type.

On the other hand, however, it very frequently affects with fatal consequences, animals imported from other parts of the country, and particularly those brought from the mountains.

The author made many examinations of the blood of apparently healthy cattle, and in 40 % of the cases, discovered the presence of piroplasmosis. The parasites are rare, only 1 in 5 to 10 fields. They occur in all the usual bacillus oval, annular or dot forms described by VELU and comparable to those assumed by *Theileria parva*, *T. mutans* or *T. annulata* and to the bacilliform piroplasms existing in Indo-China (SCHEIN), or Algeria (SOULIÉ and REIG).

Thus, the cattle of certain parts of Morocco may be permanent carriers of piroplasms, and can acquire an immunity, which appears strictly specific, to the hematozoa of the region. This immunity is relative, and may be lost in the case of weak and overworked animals

In cattle suffering from acute piroplasmosis, bigeminate pear-shaped forms associated with the shapes already mentioned, occur ; sometimes the former become very numerous, 20 % of the parasites being of this type. A similar association has been reported in Madras (CHRISTOPHERS), Japan (MIYAJIMA and SHIBAYAMA), and Indo-China (SCHEIN, " Observations sur la piroplasmose des bovidés de l'Indochine et constatation de piroplasmose chez les buffles ", *Annales de l'Institut Pasteur*, Vol XXII, No 12, p. 1005). The fact that bigeminate pear-shaped bacilli occur in the acute form of Moroccan piroplasmosis should be compared with the observations of SCHEIN, who found that, in cases of bacillary piroplasmosis in Indo-China, bigeminate pyriform bacilli appeared for a short time in the blood of animals inoculated with rinderpest, at the moment when the thermal reaction reached its maximum.

307 - **Aphthic Fever in Morocco.** — VELU H., in the *Bulletin de la Société de Pathologie exotique*, Vol. XIII, No 9, pp. 726-729. Paris, November 10, 1920

Aphthic fever (1) has long been known in Morocco, where it is called by the natives " Bou Jder ", or " Bou Jedri ", a generic term applied to all contagious eruptive diseases. It usually takes a benign form in ruminants, although twenty years ago, an outbreak of this malady apparently caused the death of a fairly large number of these animals

Cattle, when tired by the long trying journeys, under bad hygienic conditions, necessary to reach distant markets, or the port of shipment, always contract aphthic fever in a more serious form than animals remaining on the farm ; cases of death are not infrequent, while the convalescence of those cattle that recover is aways long. The same applies to the swine that are crowded together between decks on ships badly equipped for long voyages.

Though generally speaking such ruminants as are attacked by aphthic fever take a mild form of the disease, the present epidemic in Casablanca has caused a considerable decrease in the milk production of the herds of Spanish goats supplying the town with this commodity.

Young suckling animals have proved to be much more susceptible to the disease than adult stock and to succumb to it to a greater extent (2). The mortality among calves and goats is very high, the animals dying from septicaemic forms of the malady before the appearance of lesions in the mouth or feet.

In adult stock, the presence of aphthic fever is shown by unobtrusive lesions of the hoof causing very slight lameness for 3 or 4 days at the most, and by the typical lesions of the lips and tongue which give rise to a little anorexia, and to dysphagia lasting for 2 or 3 days.

(1) See *R.* Mar. 1920, No. 335 ; *R.* Sept. 1920, No. 882. (*Ed.*)

(2) See *R* Oct 1920, No. 1002. (*Ed*).

In swine the virus seems to have considerable pathogenic power. Adult animals (boars and nursing sows) only suffer from local lesions, usually of no great importance, in the mouth, teats and feet. In 1913, these foot-lesions were of a more serious nature, because the animals were out to grass. In young pigs, however, the disease occurs under very varied forms which, are often septicaemic and of exceptional severity.

(*a*) Buccal form with more on less confluent aphthic lesions on the lips, tongue, and gums

(*b*) Digital localisation with congestion of the ungual pad, aphthic lesions of the interdigital spaces, the detachment, necrosis, and very often loss of the hoof (in about 40 % of the cases).

(*c*) Digestive form with general serious symptoms and typical gastro-enteritic lesions.

(*d*) Pulmonary form with diffuse tracheo-bronchitis, and nucleus of pneumonia.

In all serious epidemics, the high mortality is to be attributed to cardiac lesions. A large number of young pigs, calves and even adult cattle die of cardiac syncope.

Death supervenes without any previous symptoms. The animals stop, appear agitated, sometimes a trembling or weakness of the hind-legs sets in, and they fall dead from heart-failure. Sometimes the cattle that succumb in this manner are in good general condition and their digital or buccal lesions are in a fair way to being cured.

Postmortem examination reveals a lesion described by KITT under the name of " spotted heart " (coeur tigré), which seems as typical as the aphthic lesion. It consists of parenchymatous, interstitial myocarditis, and microscopic investigation shows the existence of small, whitish striae, or dotted lines, or of more or less irregular zones The whole thickness of the myocardium is, however, not affected. The heart is always arrested, flaccid, in diastole.

In such cases, which are of common occurrence in young weaned pigs the treatment of the aphthic lesions is a secondary matter. What is of paramount importance, is a heart stimulant. The author has tried camphorated oil with very encouraging results.

308 - **Absorption of Aphthic Virus.** — VALLEE, H and CARRE, H , in the *Comptes Rendus de l'Académie des Sciences*, Vol CLXXII, No 3, pp. 185-187 Paris, January 17, 1921.

Researches made a long time ago on infectious anaemia in the horse and distemper in dogs, have enabled the authors to state, that filtrable viruses, like microbic toxins can adhere to the minute corpuscles in suspension in the supporting media. They have prosecuted their studies still further and found that the same power is possessed by the virus of aphthic fever. As absorbent substances the authors employed the blood corpuscles of oxen or bacteria, such as pneumococcus and staphylococcus.

They found experimentally that the aphthic virus adhering to the above-mentioned bodies is liable, under certain conditions, to total phagocytosis. Unfortunately a single inoculation with the absorbed virus is not sufficient to produce immunity.

The statements made in this paper show how careful the observer should be in inferring the presence of intra-globular virus in infections, unless during their course, the microscope clearly reveals the existence of an undoubtedly abnormal substance in the blood-corpuscles. The facts discovered make it possible to obtain, in the case of various diseases due to filtrable virus, phagocytosable suspension suitable for immunisation experiments, which it has hitherto been impossible to carry out. Finally under the same conditions, they will facilitate the preparation of sensitised viruses.

309 - **Immunity conferred by the Milk of Animals that have Recovered from Aphthic Fever.** — LEBAILLY, C., in the *Comptes rendus des séances de la Société de Biologie*, Vol. LXXXIV, No. 4, pp. 180-181. Paris, January 29, 1912.

In the course of his reseatch on the properties of aphthic virus, the author inoculated some young six-week-old pigs, which had been born after the disappearance of the disease, on farms where aphthic fever had been rife 6 months before. In certain cases, the mother had suffered from aphthic fever during the gestation period; in others, she had remained wholly immune, the piggery having escaped the epidemic that had attacked the milch cows. The virulent substance inoculated was the citrated blood of cattle taken during the fever period at the time when the thermometer registered 41°C. The amount injected varied from 5 to 10 cc. (1 cc. being sufficient for the infection of a cow). Under these conditions, the author was unable to induce the disease artificially.

In the case of a litter of pigs remaining immune throughout the course of an outbreak of aphthic fever, the only possible explanation is that this immunity was conferred upon them by the milk they were given, and which came from cows that had recovered from the disease.

Hence, the experimental study of aphthic fever has become increasingly difficult, since in times of epidemic, not only animals that have remained immune must be used, but also such as have not been fed on milk with immunising properties. During aphthic fever, milk which has been the cause of contagion and loss of life during the fever period, becomes some days after the recovery of the animal producing it, a valuable specific for the prevention of the disease in the case of young animals, and perhaps also for the treatment of the malady.

310 - **Diseases of Livestock in Morocco.** — See No. 315 of this *Review*

311 - **Dermatoryctic Mange in Rabbits and Guinea-Pigs.** — BARDELLI P. C. (Institute of General Pathology of the University of Bologna), in *La Clinica veterinaria*, Year XLIV, Nos. 1-2, pp. 19-23, bibliography of 11 works, Milan, January 15-31, 1921.

All the authors are agreed that *Dermatoryctes mutans* Ehlers (synonyms *Sarcoptes mutans* Robin, *Knemidokoptes viviparus* Fürstenberg, *Sarcoptes avium* Gerlach) is a specific skin parasite of domestic and semi-domestic birds, and in particular, of fowls of distinct breeds, in which it causes a characteristic skin disease known as " scaly-leg ". The specific nature of the parasite has been generally admitted to the extent that in the classification of Acarids, the genus *Sarcoptes* has been divided into 2 sub-genera:— (1) Fusarcoptes or Sarcoptes properly so-called, parasitic on mammals; (2) Knemidokoptes or Dermatoryctes, parastic on birds.

In many cases, a species of mange proper to mammals has been known to attack birds, but there are no exact details of the inverse transmission.

This has, however, been reported, apparently for the first time, by the author who has observed the indirect passage of *Dermatoryctes mutans* from the foot of a fowl belonging to a common breed, to the skin of all the body of rabbits and guineas-pigs, except that covering the head and feet. The disease was transmitted by the basket in which the fowls were laying. One of them was put in it to sit, and later, the basket was occupied by the rabbits and guinea-pigs for one night and the greater part of the day.

Fowls are less easily infected than rabbits, being protected by their plumage, which is thicker and harder than the rabbit's fur, and by their coarser skin.

The disease easily yields to baths of weak solutions of sulphate of potassium (5 per 1000).

312 - **The Retention of Milk** (1). — PORCHER, C., in the *Comptes Rendus de l'Académie des Sciences*, Vol. CLXX, No. 16, pp. 963-965. Paris, 1920.

Experiments carried out by the author have shown that if the milk of a cow is retained in the udder, the lactose is re-absorbed, and is eliminated by the kidneys. Osmotic pressure is maintained in the udder by an increase in the amount of sodium chloride present. With the help of these facts, the author explains the abnormal composition of colostrum and of the milk secreted under certain pathological conditions.

313 - **Experimental Researches on Colostrum.** — PORCHER, CH. and PANISSET, L., in the *Comptes rendus de l'Académie des Sciences*, Vol. CLXXII, No. 3, pp. 181-183. Paris, January 17, 1921.

Colostrum contains, in addition to the fat globules which are the normal constituents of milk, certain muriform bodies, known as DONNÉ'S corpuscles. Investigators are far from being agreed as to their significance, but the researches of several workers tend to show that they are leucocytes filled with drops of fat. This has been confirmed by the experiments of the authors.

According to them, colostrum is a result of the phagocytosis of milk previously produced. They have experimentally brought about conditions corresponding to those obtaining in the case of intramammary retention, by injecting sterile milk into the peritoneum of a guinea-pig: the process by which the milk is attacked is the same in both cases.

The histological study of the peritoneal deposits resulting from the injection of the milk, has shown that some of the leucocytes are polynucleate and the others mononucleate. Both varieties have proved themselves capable of absorbing the fat globules of the injected milk. The most important part, however is played by the mononucleate leucocytes, which seem to be the agents of slow re-absorption and lasting protection.

314 - **Reciprocal Relations Between the Nitrogenous Free Extract and the Crude Fibre in Fodders.** — HONCAMP, F., in *Fuhling's Landwirts Zeitun*, Year 69, Parts 19-20, p 378, Stuttgart, Oct 1920

The usual groups of chemical substances present in fodder, and known respectively as protein, fats and crude fibre, ash, and nitrogen-free extract are determined by the Weende Station method devised by HENNEBERG the last group being calculated by difference. This method, in spite of analytical imperfections, is, for practical reasons, always used, for as HENNEBERG states, in the case of fodders, the fraction of digestible fibre corresponds to the fraction of non-digestible extract, so that the simple determination of the nitrogen-free extract in a fodder would immediately give (with Weende method), the total quantity of extract and of digestible crude fibre present

This compensation law of HENNEBERG was at once greatly criticised; STOHMANN modified it by stating that the sum of the digestible nitrogen-free substances (especially in meadow hay) is almost equal to the amount of nitrogen-free extract and of the fats present but is influenced by the degree of the digestibility of the crude fibre.

The author's experiments show that HENNEBERG'S law of compensation does not always hold good, and further, that even STOHMANN'S amended version is not in every case true.

315 - **Stock Breeding in Morocco** (1). — MONOD, TH, in the *Comptes rendus de l'Académie d'Agriculture de France*, Vol. VI, No 36, pp 873-879 Paris, December 1, 1921

Stock-rearing in Morocco is still almost entirely in the hands of the natives. Therefore, in order to increase and improve the domestic animals of the country, it is chiefly to the natives that the Stock Breeding Service must appeal. Its efforts in this direction are the subject of the author's paper.

The reasons that hindered the development of the Moroccan herds and flocks before France assumed the Protectorate of the country are as follows: 1) The prohibition of the export of stock; 2) insecurity and the frequent raids between the tribes; 3) ignorance of all hygienic breeding rules; 4) the mortality due to parasitic and contagious diseases.

1) The export of animals from Morocco is now permitted, as far as is possible without prejudicing the development of the flocks and herds. In 1920, it was limited to 50 000 cattle and 100 000 sheep. No limit was placed on the number of swine exported. As a matter of fact, the number of head exported was much less.

2) The pacification of the country has enabled the native to increase the numbers of his stock which have risen (in spite of the increased local

---

(1) See *R.* March 1919, No 272; *R.* April 1919, No 413 (*Ed*)

consumption) from 672 483 cattle and 3 175 201 sheep in 1915, to 1 332 175 cattle and 5 079 629 sheep in 1919

3) A Service of gratuitous veterinary consultations has been organised. The Stock Breeding Inspectors make medical rounds frequenting the great regional markets, and installing themselves in some public place where they give advice, distribute medicines, and perform surgical operations. Their labours are completed by making a tour of the tribes, where the principal native proprietors are assembled in the tent of their chief.

With each of these Stock Breeding Inspectors are associated one or more native assistant veterinary surgeons recruited from the region where they will work.

In 1919, 37 220 consultations were held, and 15 000 ordinary operations and 17 754 castrations performed upon native stock. From January 1, 1921, only castrated animals will be allowed to be exported.

Great difficulties hàve been experienced in persuading the natives to provide suitable shelter for their beasts, some very encouraging results have, however, been obtained in this direction Any idea of providing reserves of food to tide over the dry season meets with stolid passive ressistance. The agricultural Hydraulic Service has already made great efforts to provide stock-rearing centres with the drinking-troughs necessary for watering the stock at all seasons of the year, but there is still a great deal to be done in this matter

(4) *Parasitic diseases.* — Parasitic cattle diseases such as echinococcosis, distomatosis, parasitic broncho-pneumonia, coccidiosis, scab, etc., are very common in Morocco, and it is exceptional for animals sent to the butcher not to have one or more of their organs affected As long as the pastures are luxuriant enough to provide the stock with sufficient food, these maladies do not greatly affect their general well-being, it is only in dry years, when the flocks and herds become thin, and therefore less resistant, that they fall victims to these diseases, but in such seasons, the mortality from these causes is often high. All that has hitherto been done is to seize and disinfect all affected organs in the abattoirs and slaughter-houses.

Contagious diseases. — Morocco, from the veterinary standpoint, is divided into a certain number of sanitary districts, each placed under the supervision of a veterinary inspector of the Stock Breeding Service.

The contagious maladies that levy the heaviest tribute upon the Moroccan flocks are bacterial anthrax, and symptomatic anthrax. A very active and incessant propaganda is carried on by the Stock Breeding Service, in order to induce both European and native owners to inoculate their animals as a preventive measure. Whereas in 1915, only 2000 animals were inoculated, the number rose to 26 825 in 1919, and since the beginning of 1920, it has attained to 69 180. A much higher figure is anticipated for 1921.

Scab is endemic among the Moroccan flocks, but is usually present in a benign form. All sheep intended for export are previously inoculated

A Research Laboratory for Stock Breeding has been founded at Casablanca. Each of the Inspectors of the Stock Breeding Service has a small laboratory at his disposal, where he can make the first bacterial diagnosis of any disease.

316 - **The Arab Horse and its Genetic Value** — BUSH-BROWN H. K., in *The Journal of Heredity*, Vol. XI, No. 5, pp. 215-227, figs. 12. Washington, D. C., May-June 1920.

The following are the anatomical differences which distinguish Arab horses from the other races: head smaller and broader; nose finer; eye larger and more prominent and alert; head articulated on to the neck at a more obtuse angle; chest broad; bones of the legs clean and very dense; etc. These differences are sufficient to mark the Arab as a separate family and the 5 lumbar vertebrae instead of the 6, common to all other horses seem to place him in a separate species. Occasionally the shortness in the back appears not in the lumbar vertebrae, but in the dorsal, 17 instead of 18; the total vertebrae number 23 instead of 24 common to all other types

Skeletons of various types have been examined at the Museum of Natural History, New York, where there is also a skeleton of a wild horse of Asia, the Prejevalsky, and also one of a Kinag (1), each with 19 dorsal and 5 lumbar vertebrae. These are considered merely individual variations, the first lumbar having developed ribs instead of the usual lateral flanges. Similar individual variation has been found in a work horse, and a Shetland pony, each with 19 dorsals and 6 lumbars. Also a Grevy Zebra which had 18 dorsals and 7 lumbars.

The short back renders the Arab horse more capable of carrying weight, and the larger abdominal capacity enables him to carry relatively more food for a long journey and he can endure privation better.

The ass, with a good weight carrying capacity has also the short back of 5 lumbar vertebrae.

The author states that the short back (*i. e.* 23 vertebrae instead of 24) is dominant only in the 1st generation of outbreeding (Arab horse × trotting stallion). In all other cases this short back is a recessive character. However, occasionally cases of atavism or reversion have been noticed, and several examples are quoted. Out breeding of the scrupulously pure Arab is therefore necessary. The Arab horse stamps his good qualities in his descendants for many generations and consequently is of distinct genetic value.

317 - **The Pony of the Island of Hokkaïdô, Japan.** — MULLER, M. (Late Extraordinary Professor of the Imperial University of Tohoka), in *Deutsche Landwirtschaftliche Tierzucht*, Year XXVI, Nos. 12-13, p 131. Hanover, November 1920.

ORIGIN. — The present ponies are not the descendants of a primitive island race. The horse, according to historical accounts, was still quite unknown to the natives only 3 centuries ago, and was imported into Hokkaïdô by the Japanese, from all the various provinces of Japan, but especially from the district of Nambon (Houshou Island). It was bred in a very primitive manner. The animals were turned out and left to themselves in pastures where there was scarcely any grass in winter, on account of the heavy snow falls.

---

(1) See R. Jan. 1921, No. 79. (*Ed.*)

MODIFYING INFLUENCES. — The horses remained the property of the Government until 1860. They were intended for riding, and distributed among the post-masters (Basho). At this time, owing to a deficiency in Basho horses, the Government authorised private breeding, which resulted in great attention being paid to the animals. Later, horse-breeding was concentrated at the three pastures at Noboretsou, Niikappori, and that of the Nanac Experiment Station.

The ancestors of the present Hokkaïdô horses, and even of those of all Japan, were bred on these pastures.

They were very strong and resistant, they were also very thrifty and had solid frames. The Hokkaïdô pony differs in a remarkable manner, both in shape and performance, from the horses formerly imported from Houshow. The variations are the result of selection, change in their manner of life, and especially of the importation of relatively good stud animals of the most different breeds from old European horse-breeding centres. These animals were crossed indiscriminately either together or with the native horses, which gave rise to an extraordinary mixtur of the most different types of horse. Breeding is carried out in a primitive manner, as the Japanese have no special zootechnical methods. As a rule, half-wild so-called studs, are met with in the country, a stallion being turned out ámong 30-50 mares, no attempt being made to regulate his service. Young mares are generally used for breeding when 17-23 months old, stallions at the age of 22-23 months.

CHARACTERS. — The author has visited districts which are still but little cultivated, and where it is possible to find horses that have not yet been crossed with European blood and thus still retain the type of the horses formerly imported. The following are the results of his researches made by measuring 107 animals: — The primitive Hokkaïdô horse on account of its very small size (height at withers 130 cm), well deserves its name of pony. The head is relatively long, and usually strong, having a slight depression at the level of the frontal bones. The lower jaw is generally very prominent. The ears are, as a rule, attached very low, and heavy and thick. The eyes are small, and have a gentle expression. Temperament docile, but easily irritated. The head is generally attached low down to a relatively strong free neck, with thick curly mane and forelock The withers are little marked, being neither high nor long and are prolonged into a sharp and relatively long back. Shoulder straight. Chest narrow, thoracic circumference of the chest relatively large. Seen from the side, the hind-limb is normally developed. The fore-leg is relatively very short and the dorso-lumbar portion very long.

These horses are usually loosely built, with a somewhat sloping croup. The solidity of the bones is good for so small an animal, since in proportion to the height at the withers, the circumference of the cannon-bone is greater than that of the Arâb horse and of certain European sub-breeds. The hair, which even in summer is thick and long, attains a great length in winter, so that some of the animals resemble spaniels. The hair is usually not glossy

The Hokkaidö pony is a very primitive creature, the true product of its environment. It is generally very resistant, thrifty, and healthy but more or less ugly ; nevertheless, in spite of its small size, it is of very great economic importance If from an absolute point of view its performance is not great, it is very considerable in proportion to the size of the animal, and the care and food it receives. These horses are able to draw and carry heavy loads over very bad roads and, as saddle animals, are not wanting in endurance. The author, taking as his basis the economic conditions. of horse-breeding and the suggestions given by the Military Authorities, sets the following as the ideal to be aimed at by the breeder of the Hokkaïdö pony : — The production of a semi-large saddle horse 145-155 cm. in height with well-shaped frame, circumference of cannon-bone 20-21 cm , shoulder long and sloping, withers long and prominent, back short, haunches strong and short, hind limbs large and muscular. The horse should be very strong and docile, with much courage and agility. Its chest ought to be deep and wide.

This ideal could be attained by using stallions 160-163 cm. in height at the withers, and with cannon-bones 21.5 — 23 cm. in circumference. The best stallion to choose would be one of the hunter type.

318 - **The Breeds of Cattle in Friuli, Italy.** — BRUMER, F, in the *Deutsche Landwirthschaftliche Tierzucht*, Year XXIV, No 24, pp 249-251 Hanover, June 1920.

The author has studied the breeds of cattle found in Friuli, a region composed partly of States recently belonging to Austria (Goritz-Gradisca), and partly of territory situated within the former boundaries of the Kingdom of Italy. The results of his observations, which have been supplemened by information given by Dr. DELLA SAVIA (Udine) and Prof. SPANN (Weihenstephan), are as follows :

The breeding conditions are not favourable Owing to the predominance of the small land-owner, intensive cattle-breeding is very difficult, especially in the districts which were formerly Austrian, and where the large estates are divided among small farmers whose tenure is guaranteed by very long leases, or even sometimes by perpetual leases.

The author distinguishes 4 breeds : — 1) The old Friulan red breed (*das alte friaulanische Rotvieh*) ; 2) the new pied, red Friulan breed (*das neu friaulanische Rotvieh*) ; 3) the breed with the characters of the «*Braunvieh* " grey-brown cattle (*das graubraune Gebirgsvieh*) ; 4) the red Carinthian breed (*das karnische Rotvieh*).

(1) THE OLD RED FRIULI BREED, formerly found throughout Friuli, is now only seen in the former Austrian part, and has disappeared in the rest of the territory owing to the creation of a new Friulan race.

As regards the origin of the old breed, opinions differ very greatly. WERNER regards it as a hybrid race resulting from the cross of red Celtic cattle (rotes Keltenvieh) with steppe cattle. On the other hand, Dr. SELVAN (Udine) traces back its origin to *Bos taurus frontosus*, and to the cattle of Berne and Fribourg. WERNER's hypothesis is borne ont by the great resemblance existing between the red Friulan breed and the neighbouring varieties in Italy, and also to the pronounced steppe-cattle character (special draught-capacity) of this red race.

The colour of the coat is maize yellow and greyish red in all shades up to dark red. The pigments are black. The head is wide, particularly at the level of the forehead. The horns are long and short. The height is great in proportion to the length of the body. The legs, especially the fore-legs, are long. These cattle are excellent draught animals. In the Valley of the Isonzo, from Goritza to the sea, the cows are also harnessed. They are not good milkers, a cow giving 6 litres of milk during the height of the lactation period is considered satisfactory. Cattle-breeding in the true sense of the word, does not exist. The bulls are used for service even before they are a year old, and sometimes serve 25 cows a day. The red Friulian cattle are very resistant and thrifty, even living on the bad hay from the marshes, which is a great advantage to the farmers of the lagoons of Grado, Aquila, and other places.

(2) THE NEW PIED RED CATTLE OF FRIULI are found in the districts of Codroipo, Latisana, Palmanova, San Daniele, and Udine as well as in a large part of those of Cividale, and San Vito al Tagliamento. Finally they are also found scattered throughout the regions of Tarcento, Gemona, Pordenone, and San Pietro al Natisone.

Italian scientists consider that the Friulian pied red cattle are descended from *Bos taurus frontosus jurassicus* (SANSON's classification), which corresponds to the *Bos taurus frontosus burgundicus* of WERNER. This seems very possible, when we realise the large number of spotted animals imported during the last decades, and notice the shape of the new breed which has the pronounced character of the pied cattle. Breeders finally, after many failures, turned their attention exclusively to importing Fribourg and Simmenthal animals and met with brilliant success.

The colour of the coat is maize-yellow, and is spotted in all shades up to dark-red. The pigments and mucous membranes are pink. The tuft of the tail and the hairs of the ears are white or red. Dark spots of colour are not allowed. The colour of the horns and hoofs is waxen yellow. The bulls measure 1.50 m. at the withers and the cows 1.40 m. The height should never be below 1.35 m.

In contrast with the old race the width, length and depth of the body are proportionate to the height at the withers. The head is not too heavy and the forehead is wide. The horns are of average length, and directed sideways and forwards. The muzzle is prominent and fleshy. The eyes are large. The skin of the lower jaw is loose and in folds. The back is straight, the tail long and remarkably slender, the dew-lap hangs low and in folds.

The pied red cattle of Friuli are multiple-purpose animals, which makes them very valuable to their owners, who are mostly small farmers. These cattle reach maturity very early, and attain their maximum weight at 5

. years of age The following Table (Journal of the Udine abattoir) shows the distribution of live weight and of net flesh : —

	Bulls	Cows	Calves (of 2 ½ months)
Live weight	1130 kg	905 kg	165 kg
Net meat weight .	570 «	450 »	132 «
» o	50 %	50 %	80 %

These animals fatten very readily and the meat is much in demand, as its flavour is excellent; therefore the exportation of fat calves plays a great part in the industry. In 1910, 50 000 calves were exported from Venetia, Tuscany, Emilia, and Lombardy. The milk yield of the pied red cattle is not so good as their beef production, although they give as much as 2000-2500 litres annually, the fat content being 3.5 %.

Milk that is not used for rearing calves, is taken by the numerous dairy syndicates Although the new breed does not appear to have inherited the working capabilities of the old breed, these cattle are nevertheless good draught animals.

Throughout Friuli, the cow is chiefly used for ploughing and other field-work. The proportion of cows and bulls thus employed is as 4 : 1

By the introduction of a system of licences for bulls, breeding became a more serious business In addition to many private bull owners, there are now a large number of breeding societies that regularly import bulls from Switzerland. During the last ten years, there has been a marked inclination towards greater freedom in the importation of Swiss stud cattle, the principle adopted having been to maintain the present type by careful breeding and the use of suitable bulls. The improvement of breeding, as well as its supervision, is in the hands of Provincial Commissions appointed by the State and of the Friulan agricultural Society.

THE GREY BROWN CATTLE are chiefly seen in the Sacile district, and the neighbouring parts of Pordenone and Aviano. On account of their strong constitution and solid hoofs, these animals are very well suited to working in mountainous regions, and are therefore preferred to the Simmenthal breed. The grey-brown cattle much resemble the brown Schwyz breed, but whereas the latter are rather short and thickset, and are only dual-purpose animals, milk production being predominant, the former, on the other hand, are taller, and have a longer body, being thus suitable for every purpose, and are especially good draught cattle.

THE RED CARINTHIAN BREED (1) is common in the following districts of Upper Friuli : — Tolmezzo, Ampezzo (Carnia), Moggia, Spilimbergo, Maniago, Tarcento, Gemona, and Cividale. As regards its origin, German and Italian technical experts differ, and whereas the former, judging by the general appearance, class this breed among the group of the representatives of *Bos taurus longifrons alpinus* (*brachycerus*), the latter consider it nearly related to the Müllthal race.

---

(1) *Suddeutsche Landwirtschaftliche Tierzucht*, Year X, No 17, Nov 1915 · Dr. SPANN (Weihenstephan), " Einiges uber die Viehzucht in Udine unter besonderer Berucksichtigung des karnischen Viehs ". (*Ed*)

The coat of the Carinthian cattle is of different shades of red, with a light stripe. The horns are yellowish-grey at the base, and have black tips. The height at the withers is as much as 1.20 m., the live weight of the cows varies from 250-300 kg. and the milk yield never exceeds 2000 litres.

319 – **The Efficiency of Purdue Calf Meal as a Milk Substitute in Calf Feeding.** — SPITZER, G., and CARR, R. H. (Purdue University Agricultural Experiment Station), in *Bulletin* No. 246. pp. 1-8, figs. 2, Lafayette, Indiana, 1920. and reviewed in *Experiment Station Record*, Vol 43, No 91, pp 875 876 Washington, 1921.

Purdue calf meal consists of maize meal, linseed meal and liquid beef blood (8 : 1 : 12) plus steamed ground bone to the extent of 1 %. This is dried for from 4 to 6 hours at a temperature not over 140°F, and then ground.

An hour or so before feeding it is mixed with 4 times its weight of warm water, forming a jelly. This is again diluted at feeding time and is fed at blood heat. Liquid blood meal thus prepared, was more readily digested than commercial dried blood.

A group of 36 grade Holstein calves varying in age from 10 to 20 days, and in weight from 85 to 126 lb. were fed for 140 days. A lot of 12, receiving whole milk throughout, showed an average gain of 1.91 lb. per head. A similar lot fed on skim milk, after the first 10 days showed an average daily gain of 1.73 lb. and a third lot fed on Purdue calf meal gained 1.18 lb.

Ground maize and oats (1 : 1) was fed as a dry mash to each lot, and for part of the time the calves had access to bluegrass pasture (*Poa pratensis*) or clover hay.

The calf meal lot were thrifty and remained in good condition, and during 6 months of pasture following the feeding period, they gained about the same amount as the other lots.

320 – **Experiments in Feeding Maize Cake to Milch Cows in Italy.** — BONOMI, L., in *Il Coltivatore*, Year LXVII, No 4, p 110, Casale Monferrato, February 10, 1921.

The author has studied, at the Udine Agricultural Station, the effect of adding maize cake to the ordinary ration of milch cows in different stages of gestation and lactation, and has obtained the following results:

(1) At an advanced stage of gestation (7 months), the milk yield of a cow receiving 500 gm. of cake daily, diminished (this however, may well be attributed to the fact of her being in calf). No increase in live-weight was observed.

(2) In the early stage of gestation (3 months), the weight and milk yield of the cow fed 500 gm. of maize cake a day increased.

(3) At the post-puerperal stage (1 month), the amount of milk increased progressively in proportion to the gradual increase of the quantity of cake given (from 1 to 2 kg.). The fat content of the milk was maximum when 2 kg. of maize cake was added to the ordinary ration. Hence the addition of maize cake, at a given time, improves milk production.

321 – The Feeding of Dairy Cattle with Guango Pods (*Inga Saman*) in Jamaica. — COUSINS, H H, in *The Journal of the Jamaica Agricultural Society*, Vol XXIV, Nos 6-7, p 157, Kingston, June-July 1920, and *The Tropical Agriculturist*, Vol LV, No 5, p 342 Peradeniya, Ceylon, November 1920

The Government Farm at Hope has had extensive experience of the use of Guango (*Inga Saman*) pods for feeding dairy cattle during the past 3 years, and it is due to this valuable material that 300 head of cattle were kept on a little over 200 acres of land at Hope in 1919 and 1920

Guango was fed freely to all classes of cattle including calves, and it is considered that 15 lb. per day is a reasonable allowance for a mature animal. Many cows will, however, eat 25 lb. per day without injury In 1919, 278 tons of pods were stored and during the year about 310 tons were actually fed to the cattle.

The author emphasises the fact that guango is dangerous if fed under the following conditions: 1) Mixed with silage; 2) after the pods have fermented, as the pod is a saturated solution of sugars and if they get wet they ferment and poisonous effects result from their consumption by cows, 3) in excess, which is liable to cause skin eruption and renders the animals no longer good dairy stock, 4) crushed and allowed to ferment The kernels of guango are astringent and readily fermentable, and cause irritation to the intestines and possibly subsequent death It is now considedered that unless crushed with corn cobs or megass guango and the milk product dried for some hours at 150°F it is safer not to crush the pods, but to feed them whole.

322 – Influence of the Time of Calving Upon the Annual Milk Production of Cows. — SCHMIEDER, in the *Deutsche Landwirtschaftliche Tierzucht*, Year XXV, No 5, p 46, Hanover, January 1921

Experiments based upon three factors, which were, as far as possible, the same in the case of the respective herds· — 1) The dates of the beginning and end of the grazing season, 2) the annual milk yield; 3) food. The average annual milk yield was 2112 kg for herd A, and 2241 kg. for herds B, C and D.

The cows were grouped according to the date of calving Their annual milk production is given in the following Table.

		Stall fed Time of calving April May 2 *months* before being put out to grass	Beginning of grazing season Date of calving June	Middle of grazing season Date of calving July-Sept	End of grazing season Date of calving Oct Nov.	Stall-fed after grazing season	
						December to January	February to March.
Herd A Total 71 cows	Number of cows average . . .	6	16	17	9		17
	Milk yield . .	2418 kg	2051 kg	2142 kg	2280	2081 kg	2133 kg
Herds B C-D Total 82	Number of cows	14		19	18	14	
	Average of Milk	2380 kg	2075 kg	2177 kg	2241 kg	2326 kg	2264 kg

Herds B, C and D, being too small to furnish a large enough number of cows for each group, were examined together. Cows with an extremely high or very low milk yield were not taken into consideration.

As the Table shows, the best time for calving is during the 2 months before the cows are put out to grass, and what is rather surprising, the worst time is the beginning of the grazing season.

This fact the author explains from the physiological standpoint. He considers that it is because the mammary glands, which had already become less active are roused to greater activity by the change of diet.

323 - **Pea Straw for Fattening Cattle in the United States.** — HACKEDORN, H., in *The Breeder's Gazette*, Vol. LXXVII, No. 15, p. 966. Chicago, April 8, 1920.

Feeding experiments carried out at the Washington Experiment Station for 95 days with 4 uniform lots of 6 high-grade Shorthorn steers. Each lot received the same mixture of concentrated feeds: steam rolled barley + cottonseed meal, ratio 7 : 1 (in pounds).

The results are given in the appended table.

	Pea straw	Alfalfa	Pea straw + alfalfa	Pea straw + maize silage
	lb.	lb.	lb.	lb
Av. initial weight	950.5	950.7	959.1	956.8
Av. final weight	1182.3	1181.3	1195.8	1215.6
Average grain	231.8	230.6	236.7	258.2
Av. daily grain	2.44	2.43	2.49	2.22
Av. daily ration				
Grain	15.06	15.07	15.07	15.08
Pea straw	18.96	—	9.90	8.67
Alfalfa	—	14.74	7.34	—
Maize silage	—	—	—	20.88
Feed per 100 lb. grain				
Grain	617.1	620.0	604.2	555.4
Pea straw	766.6	—	397.0	319.4
Alfalfa	—	606.7	295.0	—
Maize silage	—	—	—	769.3
Cost of 100 lb. grain	$ 25.92	$ 28.68	$ 26.78	$ 24.33

The author considers as a result that the pea straw for fattening cattle is about 30 % less efficient than the alfalfa.

324 - **Tests in Winter Feeding of Lambs.** — LONSDALE, T. W. (Manager of the Moumahaki Experimental Farm), in the *New Zealand Journal of Agriculture*, Vol. XXI, No. 4, p. 203. Wellington, Oct. 20, 1920.

Report of a test experiment with white face lambs, which had not previously received artificial good. The animals were divided into 4 groups: 1) those turned out on swedes, with the main flock of lambs, which received in addition as much chaffed pea straw as the animals could consume; 2) those on pasture and given lucerne hay *ad lib*; 3) those on pasture with other sheep; 4) those on pasture and fed with ordinary hay.

The average weight per head at the commencement and end of the trial, (May 25 to July 24) together with the respective gains for each group were as follows :—

Group	Weight per head	Gain per head
	lb	lb
1	64 — 75.6	11.5
2	63.2 — 74.3	11.1
3	54.2 — 64.4	10.2
4	62.3 — 73	10.7

It is evident that while all the lambs made ordinary winter growth there was very little difference between any of the groups The author indicates that the results of this trial must not be taken as conclusive, but they point to the fact that with judicious treatment, the deathrate of young sheep during their first winter can be considerably minimised

325 - **Poultry Keeping in Fruit Plantations.** — GARRAD, G H, in *The Journal of the Ministry of Agriculture*, Vol XXVII, No 4, pp. 350-359 London, July 1920.

The author's object is to show that poultry keeping and fruit growing can be made a very profitable combination. A detailed report is made of the work carried out on 14 ½ acres of land in the south-east of England on a steep hill facing south. The author himself checked the accounts of the said fruit farm.

The results supported the opinion expressed by THEOBALD, the Agricultural Entomologist, that the employment of poultry as a means of checking some of the insect pests of fruit is a subject that deserves far more attention than it has hitherto received. As an example of what fowls eat in an orchard, he gives an analysis of the crop and gizzard contents of a White Leghorn chicken of 5 weeks old, namely 190 pear midge maggots, 127 aphides, 12 red ants, 2 tortrix caterpillars, and 1 beetle in addition to grain, seed and other foods. A Red Sussex pullet contained 14 leather jackets, 10 fever flies, 2 wireworms, 4 cutworms, 5 beetles, 50 ants, 7 woodlice, 4 slugs, 1 millipede and 20 larvae of the winter moth The light breeds, such as Leghorns, hunt the best and go further afield than the heavy breeds such as Wyandottes and Orpingtons, and in orchards of standard trees they are therefore the most suitable breeds to use for this purpose.

With reference now to the fruit farm in question, the owner does not believe in deep digging because it prevents the fine feeding roots of the trees from working their way close up to the surface of the ground where they can make full use of the poultry manure Also a shallow tilth is preferred to prevent the winter caterpillars that fall from the trees, burying themselves deeply in the soil The practice of walking through a plantation and shaking each bush is recommended, as the poultry follow and consume each caterpillar as it falls to the ground. Only young chickens are allowed to run among the gooseberry bushes, the hens being confined in coops but hens properly fed will not attack the fruit (nor even currants until they begin to colour), and do a great amount of good by picking off the scale insects. They are also invaluable in dealing with raspberry and loganberry beetle, but do not attack the hairy sawfly caterpillars on gooseberries, and only cuckoos will deal with these. Windfall apples will, of course be attacked by the birds but this is unavoidable.

No expensive poultry houses or appliances are kept and nearly all are home made. A 100-egg incubator has been used on a few occasions in the past 2 seasons, but with that exception all the eggs have been hatched out under hens The breeds kept are the White Wyandottes, Buff Orpingtons and White Leghorns; all general utility fowls.

From the balance sheet it is evident that the poultry proved exceedingly profitable. The 5 years under consideration have all been years of war, and the prices have consequently been high in all directions. It is interesting to note that on November 1, 1914, HALL the owner of this farm, possessed 152 head of poultry, of which 138 were hens and pullets, and that in 5 years, he sold:—

	£	s	d
98 761 eggs for domestic purposes at 3*s*. 2*d*. per doz. .	1 240	1	7
12 557 eggs for setting at 4*s* 6*d*. per doz.	234	14	4
657 infertile eggs at 1 1/2*d* each	4	9	0
1 811 day old chicks at 1s 4*d*. each	106	11	8
2 216 birds of various ages at 3*s*. 11*d*. each	439	9	10
Total	2 025	6	5

His stock at the end of 5 years had increased from 152 to 406 birds, and his food bill for the 5 years amounted to £ 1008, 13 2d.

For 1 year (Nov. 1918 to Oct. 31 1919) the profit (rent and labour deducted) was £419, 19s. 1d.

326 – **Comparison of Poultry Breeds.** — BORGH, O. Y., in *Minnesota Agricultural Experiment Station Report of Grand Rapids Substation*, 1915-1919, pp. 71-72.

The following table summarizes 3 years records of production. The flocks were managed as in a commercial establishment and consisted chiefly of pullets and yearlings.

Breed	Eggs per hen	Feed consumed per hen	gs per of feed	Average weight of an	t of egg hen	weight hen	Ratio body weight to weight of eggs	
		lb.		ounces	lb.	lb.		
Single Comb White Leghorn	121 91	58.50	2.35	2.15	16.38	3.90	1 : 4.20	3.12
Rhode Island Red	104.82	97 98	1.08	2.12	13 89	5.80	1 : 2.40	1.25
Barred Plymouth Rock . .	86 30	86.73	1 00	2.02	10.89	6.70	1 : 1.63	0.85
White Orpington	81.78	115.23	0.71	2.02	10.32	7.10	1 : 1.45	0.19

327 - **Experiments in Breeding Bivoltine Silkworms in Brianza, Italy.** — PODESTÀ, D., in *Il Coltivatore*, Year LXXVI, No. 35, pp. 946-948, 1 fig. Casale Monferrato, December 20, 1920.

The author obtained 1 ounce of the eggs of the " White Japanese " bivoltine breed of silkworms sent to an Italian sericulture Commercial House. When the silkworms hatched out, he divided them into 4 lots, sending 3 of them to peasants, and keeping the 4th to rear himself at Garlate (Como). Of the 3 lots entrusted to peasants, 2 were wholly or mainly destroyed by the cold, while the 3rd barely yielded 700 gm. of cocoons, and 300 gm. of "*strusa*". The lot reared by the author only produced 1500 gm. of cocoons, and 100 gm. of waste silk. The development of the silkworms was irregular, the cocoons being of very variable dimensions, but as a rule, quite small (about 1100 going to make a kg.). The spinning results were unsatisfactory, 41.20 kg. of waste silk being obtained per 100 kg. of spun silk. The silkworms began to hatch out at the end of August, and the moths emerged from the cocoons at the end of November. These somewhat discouraging results convinced the author that it is not advisable to try and rear bivoltine silk worms, where there is any risk of sudden falls of temperature in September. Better results might, however, be obtained, if the larvae were hatched from the end of July to the beginning of August. This plan would also have the advantage of making the vintage coincide with the time of the second rearing, which would be a convenience to the workers.

FARM ENGINEERING

328 - **Results given by Tractors in Belgium.** — LEPLAE, E. (Professeur à l'Université de Louvain, Rapporteur de la Commission de Motoculture du Conseil superieur de l'Agriculture, in the *Journal de la Société nationale des Agriculteurs de Belgique*, Year III, No. 7, pp. 49-53. Brussels, Feb. 12, 1921.

By command of the Conseil superieur de l'Agriculture an enquiry was made as to the results given by tractors in Belgium.

A series of questions were sent out to a great number of farmers who were known to use tractors, and by December 1, 1920, about 90 answers were sent in.

The abstract of these answers is not yet finished, and the present communication only gives the most interesting points, viz., ease of working, frequency of stops, cost of repairs, probable influence of motor-cultivation on the use and upkeep of horses and draught cattle, work other than ploughing, areas cultivated, consumption, etc.

The inquiries sent out did not refer to mechanical traction only, questions also being asked about draught animals, in order to compare costs of work and upkeep between draught animals and tractors.

The replies are not yet tabulated. The replies analysed are here presented to show as clearly as possible the conclusions drawn from them.

I. — SATISFACTION GIVEN BY THE WORK OF THE TRACTORS. — *Question.* Are you satisfied with the work of your tractor? If not, state your reasons. Will you continue to use a tractor?

The replies were remarkably unanimous. Out of 45 farmers, 42 declared themselves satisfied or very satisfied. Only one wished to part with his tractor which appeared to be in a very bad condition. Others complained of the cost of petrol, the impossibility of ploughing without ridges, and in one case where the complaint was insufficiently deep ploughing, the farmer wanted to plough to a depth of 30-35 cm.

Out of 45 farmers, 43 intended to continue using a tractor. One exception found the cost of petrol too high and the other although possessing a good make of tractor, said it had never worked properly or given good service.

II. — IMPORTANCE OF THE WORK DONE BY THE TRACTORS. — From the 67 replies received it appeared that the tractors were largely used, for areas from 50-150 hectares, the usual areas for work in silt-soil districts. Only in one case out of 45 was the tractor reported to be unsatisfactory.

III. — NATURE OF THE SOIL. — The 42 farmers who gave the nature of their soil are divided as follows :

4 farms with sandy silt loams
5 » » light » »
11 » » heavy » »
17 » » clay soils
5 » » heavy clay soils

It thus appears that tractors are most used as might be expected, in regions with heavy soils.

IV. — AREAS OF THE FIELDS. — The fear has been expressed that tractors cannot be advantageously worked on small areas. However none of the correspondents found difficulty in working such areas, as 15 farms had plots of 3 hectares and 5 had plots of from 1-1.5 hectares. It can be admitted that the tractor works under normal conditions on 1 hectare plots. The length of the furrows is the only consideration of importance as regards this, for if they are long, the tractor will lose less time at the headlands. If plots are joined they should be made as long as possible.

V. — WORK DONE BY THE TRACTOR. — Ploughing is the principal work to which tractors are put ; the depth of ploughing varies from 15 cm. for cereals to 20-25 cm. for beet. The following table enumerates the different kinds of work in which the tractors were employed and the number of farms requiring each kind of work. Then table is compiled from 45 replies.

Stubble ploughing . . .	11 farms	Harvesting.	18 farms
Weeding, disking	19	Threshing	8
Harrowing	17	Grinding.	2
Rolling	9	Pumping	1
Weeding, rolling and harrowing combined	7	Cutting	1
Sowing	2	Sawing	1
Mowing.	3	Traction	1

The use of tractors is now well understood on certain farms where the work is combined work *i. e.* weeding, rolling and harrowing, and where the tractor is used for harvesting and threshing. In order to use a tractor economically it must be given sufficient work, such as pulling a multi-furrow plough, a large disc harrow or scarifier, or a combination of a scarifier pulling a roller and a harrow, or two mowers or harvesters, etc.

The tractors, being provided with strong machines and usually developing 15-20 H. P., can all be used to pull the beet wagons in the fields or along the roads. They have been successfully used for lifting beets, by means of lifters taking 3 rows at a time.

VI. — AMOUNT OF WORK DONE IN A DAY. — The area worked in a 10-hour day depends very much on the resistance of the soil, and the nature of the work. In the 45 farms mentioned above, the area worked per 10 hour day, the results, using one tractor in each case, were as follows:

Ploughing, according to the nature of the soil, from 1-3 hectares.
Stubble ploughing, 2.5-8 hectares.
Scarifying, disking, 4-12 hectares.
Rolling, 5-10 hectares.
Harrowing, 5-20 hectares.
Rolling and weeding combined, 5-10 hectares.
Reaping, 3-7 hectares.
Mowing, 3 hectares.
Threshing, 120-200 sacks.

The big differences between the area worked per day of light work (scarifying, rolling, harrowing, reaping) is due to the fact that some farmers use the tractor to pull narrow horse implements, whereas others use wide implements that cover a much greater surface per day.

VII. — FUEL USED. PRICE OF FUEL AND OIL. — Out of 47 farmers that used a tractor, 15 used petrol and 32 paraffin. Petrol cost 2 fr. to 2.40 fr. per litre, and paraffin cost 1 fr. to 1,50 fr. per litre, generally 1.12 fr. to 1.25 fr. per litre. Lubricating oil cost from 2.25 fr. to 4.25 fr. generally 3.50 to 4.25 fr. per litre. The consumption of petrol, paraffin, and lubricating oil varies very much according to the depth of work and nature of the soil.

Ordinary silt loam. — Ploughed 20 cm. deep, 2.5 hectares per day, 30-35 litres of petrol per hectare per day.

Clay or heavy silt loam. — Ploughed 20 cm deep, 2 hectares per day, 35-40 litres of petrol per hectare per day.

Usually less petrol than paraffin is used, but the difference is not more than 5 litres per hectare, so that, taking into consideration the present prices, it is cheaper to use paraffin. Most petrol tractors can run on paraffin if the carburettor is adjusted.

The quantity of petrol used per day to start tractors that run on paraffin varies from 2-8 litres, but these figures are not of much value as the exact amounts were not ascertained very accurately; 4-5 litres per day should be enough.

The lubricating oil consumed varies from 2-10 litres per day. Such great differences should not occur and are due to inexperienced drivers. Oil is now very expensive and great care in its use should be taken. According to the statements received, the consumption should not be more than 3-5 litres per day, and in some cases may even be less.

VIII. — EASE OF CONTROL. — In 44 cases out of 45, the farmers found the tractors easy or very easy to handle. Complication in the tractor is more apparent than real and offers no obstacle to agricultural work; the same applies equally to binders.

IX. — DRIVERS AND ENGINEERS. WAGES. — In order to obtain information as to the knowledge and skill of the drivers, the farmers were asked whether they employed a farm hand or a driver mechanic to drive their tractors. Out of 45 who answered, 25 employed a farm hand as driver, 4 employed a labourer who had been through a course of mechanics or had worked in an agricultural engineering works, 7 had engaged a driver-mechanic, 5 employed their sons, and 1 drove the tractor himself.

The farm-hands received 15-20 fr. a day, or 12 fr. plus food and lodging. Some farmers paid a fixed wage of 10-15 fr., plus a bonus of 2 fr. per hectare ploughed, 0.50 fr. per hectare weeded, harrowed, or rolled. Some paid 7-10 fr. plus food. Some gave the same wage as the labourer plus emoluments, such as clothes or supplements. The work is looked upon as less tiring than driving horses.

The labourers who had been through a course of mechanics were paid the same wages as the others; the replies unfortunately, apparently show no difference as regards this. The driver-mechanics received 225 to 450 fr. per month, plus food, lodging and heating. This corresponds to 9.37 to 18.74 fr. per day per month of 24 working days.

X. — FREQUENCY OF STOPS AND ACCIDENTS. COST OF REPAIRS. — Although there were not many replies and although the tractors in question had not been in use for more than 6-12 months, it clearly appears that the wear depends chiefly on the area worked. On a farm of 200-400 hectares, a tractor ploughs many hectares per annum, wears out more rapidly, and costs more in repairs and maintenance than when working an average 50-100 hectare farm.

The skill of the driver has a great deal to do with the number of accidents. The author has here grouped the information obtained according to the different classes of persons employed as drivers.

Ordinary labourers. — Tractors of all makes driven by ordinary farm labourers and in use only for from 2-6 months (1920) required, as a rule, no more than the usual slight repairs, due to wear and tear. But with tractors employed for about 12 months (autumn 1919, spring and summer, 1920) on farms of 100 hectares there was an average of 2-10 accidents (parts broken, strained or worn), costing altogether 250-700 fr.

Some tractors of the same make working 300-400 hectare farms cost as much as 1600 fr. for repairs during their first year.

Labourers who had received instruction. — Accidents were not numerous, save in one case when the tractor was laid up 10 times, costing 1200 fr. for repairs and losing $^{1}/_{10}$ of the usual time (the farm covered 400 hectares).

Farmers' sons. — Accidents were as frequent as with farm-hands. During 20 months, and with farms of 80-100 hectares the cost of repairs was 700-1000 fr.

Driver-mechanics. — No tractor had been working in their hands for more than 6 months and there was no need for repairs.

XI. — ADVANTAGES OF THE USE OF TRACTORS. — The replies showed that there were many advantages, which can be classified as follows:—

Manual-labour. — There is a great economy in manual labour. The tractor will work 2 hectares per day, whereas a 3-horse team on the same land will work 40 acres, so that 5 teams are required to do the work of one tractor. The tractor required one man, and therefore replaced 5 three-horse teams or 5 men and 15 horses. The tractor also tends to obviate the need of keeping extra hands in readiness for the busy seasons. Again other correspondents stated that with the same number of men they could work a much larger area.

Teams. — Most of the correspondents stated that the tractor replaced a certain number of horses or oxen; some have given up horses, but most have eliminated draught cattle.

The estimates of the number of horses replaced were very varied, some estimating that the tractor replaced 4-6 horses per 110-hectare farm, others that it replaced 6-9 horses on a similar farm. This gives a saving of about 60-90 fr. a day for food.

The number of oxen replaced by a tractor was from 9-12. One gave up all his oxen on a 165-hectare farm; another eliminated 10 oxen on 84 hectares, and a third all his oxen on a 315-hectare farm.

The tractor lightens the work of the horses, gives rest to the brood-mares, and facilitates the work at times of harvest and ploughing. Again they save the extra ration needed by the horses at these times, which amounts to a great deal in a large stable. A supplement of 3 kg. of oats per horse for 3 months of the year represents for 18 horses a cost of 5000 fr.

Quality of the work. — Most of the replies claimed as advantages the rapidity of the work, the possibility of stubble ploughing immediately after the harvest, and the possibility of ploughing and preparation of the land at the right time. Especially is this useful when the weather is bad, as, in a few fine days, a tractor, can prepare the land very quickly, especially if wide implements are used, as many farmers do.

The correspondents were very satisfied with the quality of the work, and 38 out of 46 stated that the ploughing was as good or better than that done with horses, and that the greater speed of the tractor pulverised the earth better. Eight replied that horses did the work better, because it is more difficult to regulate a 3-furrow plough, whilst the mould-boards were not quite suited to the silt-loam regions of Belgium. Seven farmers stated that the manure was not buried as well, but that this was the fault of the plough, and not of the tractor. When using a tractor for harvesting, 18 farmers stated that the work was done perfectly, and one correspondent stated that this was because of the regularity of speed of the tractor. Only on ereply was unfavourable, the fear being the wear would be too great owing to the speed of the tractor.

The 20 correspondents who had not yet used the tractor for harvesting stated that they were going to do so, and had no doubt that the work would be very well done.

XII. — DISADVANTAGES AND DIFFICULTIES IN THE USE OF THE TRACTOR. — In reply to this there were 45 very interesting replies, 19 stating that there were no disadvantages and no difficulties. The others pointed out the following disadvantages:—

Cost of the tractor too high (2 replies).
Price of spares excessive (1 reply).
Cost of petrol, paraffin and oil too high (8 replies).
Difficult to find good driver-mechanics (6 replies).
Mechanism too complicated (1 reply).

Consumption of fuel too high (1 reply).
Wear of tractor too rapid (1 reply).
Forced to plough without ridges (3 replies).
Tractor goes badly in damp weather (1 reply).
Tractor does not bury strawey manure well (1 reply).
Weight of tractor is not enough for carting on the roads.
The tractor suffers when run over paved roads.

XIII. — WEAR AND TEAR. — The tractors in Belgium have not been at work long enough to judge their resistance to wear and tear. This question was asked in the following terms:— For how many years do you think that your tractor will work without needing serious repair?

Out of 43 replies, 16 had formed no opinion, 4 hoped that the tractor would last from 6-10 or 15 years, 9 counted on 4-5 years, 12 judged 3-4, and 2 only counted on 2-3 years' service. The average estimate was therefore well over 4 years.

It is concluded that, with tractors which have worked for more than a year, or over a large area, economy in work largely depends on the resistance to wear of the tractors, and the farmer should therefore buy, machines that are carefully and strongly built.

329 - **The Sinking and Adherence of Agricultural Tractor and Motocultivator Wheels.** — LOMBARDI, M., in the *Reale Istituto Lombardo di Scienze e Lettere, Rendiconti*, Series II, Vol. LIII, Parts 10-11, pp. 415-434. + 6 figs. Milan, 1920.

The author studies the nature, relation and dependence of the different factors which oppose the progress of the wheels of agricultural machines, and he examines mathematically the sinking of the wheels, the influence of the irregularities of the soil, other resistances of the soil, the action of grips, passive work due to the grips and the effect of grips on adherence. He demonstrates how these resistances can be theoretically studied and determined by simple analytical expressions and methods, the comparative importance of the different passive resistances — the necessity, especially as regards strakes for gripping, of judging the capacity and usefulness of a plough in relation to the conditions to which it is suited, and to guard against the error of thinking that it will give satisfactory results under any conditions. Finally the author insists on the urgent need for establishing the laws of variation and the values of the coefficients of inelastic and elastic compression of adhesion, of rescission, and of soil friction, especially with regard to an ordinary wheel that is moving under load.

Only then can accurate practical formulae be evolved which will enable the maker to design and the agriculturist to choose the machine that is most suited to particular types of work as regards the wheels and gripping pieces applied to them.

330 - **Safety Pendulum for Tractors.** — DESSAISAIX, R., in the *Journal d'Agriculture pratique*, Year LXXXIV, No. 40, pp. 397-398 + 1 fig. Paris, Nov. 11, 1920.

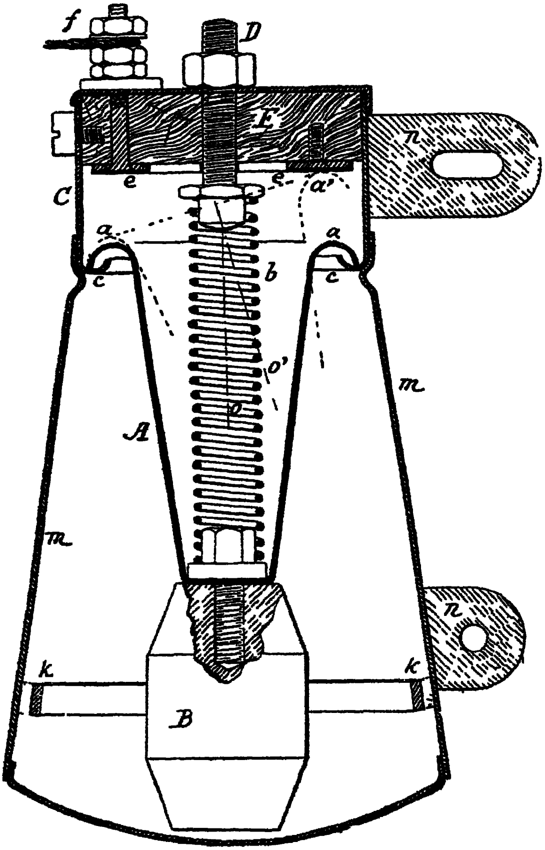
When a tractor is required to furnish a pull that rises momentarily above a certain limit, one of three things happens:—

(*A*) The motor is not powerful enough:

1) The maximum effort has the effect of braking and "blocking" the engine, which stops suddenly, and usually damages the drive of the fan when operated through gears.

(*B*) When the motor is very powerful, 2 things may happen:

2) When the soil is relatively open or damp, the driving wheels slip and the grips dig up the ground, burying the wheels until the frame or other part stops the machine from sinking further



Safety pendulum tor tractors.

3) If the soil is resistant, the driving wheels are gripped and stop turning, and the tractor tends to rear up.

In each case it is necessary to unhook the tractor before the engine is restarted.

The third case is dangerous if the driver has not the sense to throw the machine out of gear or stop the engine before the tractor tips up. Machines with powerful engines and a light forecarriage are specially liable to tip up and injure the driver. In order to prevent accidents like this M. E. FEUILLETTE, a farmer of Perthuis (Saint-Maurice-sur-Aveyron, Loiret), has invented a safety pendulum which automatically cuts off the ignition when the tractor tips up to a dangerous angle.

The principle of this pendulum is shown in the diagram.

A pendulum *B* is solid with an inverted cone *A* with its upper edge *a* flanged, and resting on a collar *c* of the cap *C*, a spring *b* bolted to the cap at *D* steadies the pendulum against vibration. The upper part of *C* is closed by a cover *E* which bears an insulated ring *e* which is connected through the terminal *f* to the coil of the magneto. When the tractor tips, the pendulum swings out of the normal axis *o* to *o'* and the lip *aa* of the cone rises to *aa'*, thus making contact with the ring *e*, so that the ignition is at once suppressed automatically, thus stopping the engine.

The part *ef* can be replaced by an insulated ring *k* connected to the magneto, — contact being obtained through a point on the side of the pendulum *B*. The instrument is encased in *m* which is fixed by means of *n* to a suitable place on the frame. The same principle can be used, by means of levers and cranks, as an automatic control of the gas inlet, so that when ascending a rise, more power is given, and when descending, the gas is shut off in proportion to the steepness of the slope.

331 - **Utilisation of Automobile Engines.** — RINGELMANN, M, in the *Journal d'Agriculture pratique*, Year LXXXV Vol. 1, pp. 12-16, + 5 figs. Paris, Jan. 6, 1921.

The utilisation of old touring-car engines may be of interest to country agricultural work-shops, repair-shops, and for grinding and crushing grain, in cider factories, for pumping water, etc.

It is preferable to remove the engine from the chassis and bed it on a suitable frame resembling that used as a bed for testing engines in a motor works. The frame may be made of double *T* irons, or of hard wood, and the engine bed bolted on to it. For certain kinds of work it is best to gear the engine down. This can be done by keying a pinion on to the main shaft geared to a counter shaft such as is used in electric dynamo plants. It is better to have spur gearing which is silent or a green leather pinion. The countershaft, running at, say, 250-300 revs. per min., carries a belt pulley.

The fan-cooled radiator should be replaced by a tank placed laterally and high up. But if the water is circulated by a pump, this system should be retained as the hot water discharge pipe is not wide enough to allow a rapid enough flow of cool water if the thermosiphon is to be used

The exhaust expansion box should be done away with as it always causes a certain amount of back pressure, and a wide pipe should be substituted, that is sufficiently long to prevent flames issuing that might cause fire. By doing this the author increased the power of an old engine by 10 % at the Station d'Essais de Machines, without increasing the fuel consumption. The engine may be set on top of a brick platform about 45 cm.

high, so that it is easy to turn the starting handle, or it can be mounted on a platform provided with 4 cast iron rollers, or on a trolley. Light, high speed engines, weighing not more than 20 kg. per H. P. can only be kept steady by weighting the frame with stones, wooden boxes filled with earth, etc.

When the capacity of the engine is known, it is advisable to set up a power plant on one frame, *i. e.* pump, saw, generator, etc. It is better to use a carburettor which can use paraffin instead of petrol, or better still, a poor gas generator, to reduce the cost of fuel, especially under present conditions.

332 - **Harvest Machine for Camphor.** — See No. 294 of this *Review.*

RURAL ECONOMICS

333 - **Cost of Threshing in France.** — RINGELMANN, M., in *Journal d'Agriculture Pratique*, Year LXXXIV, Vol. II, No. 46, pp. 389-391. Paris, Nov. 11, 1920.

The author estimates the cost of threshing per hour of a set comprising 2 men (mechanic and feeder) provided by the contractor with the machine, fuel and lubricants, the price being relative to a full day's work, the cost of transport from place to place being accounted for separately, whilst the transport of coal and water and supplementary manual labour are charged to the farmer.

The author takes the material at pre-war price, the locomotive, at 5 500 fr. and the thresher at 3 000 fr. at the most, costing in all 8 500 fr. The annual expenses for amortisation, upkeep, and repairs, taken at 20 % of the first cost, is 1 700 fr. This sum is distributed over 500 working hours, i. e. 3.40 fr. per hour. A 6 H. P. locomotive consumes 2.2 to 2.5 kg. of good quality coal per H. P. per hour, or a maximum of 3 kg. Before the war, lubricants cost 0.60 fr. per kg., labourers 0.80 fr. per hour, plus 6 % for insurance against accidents totalling 0.85 fr. per hour.

The author bases his calculations on the use of old machines, as the are very few 1920 models in use (these cost 15 000 fr. for the locomotive, 5 000 fr. for the thresher, in all 20 000 fr. representing an annual cost of 4 000 fr., and 8 fr. per working hour). The fixed expenses of old machines remain at 3.40 fr. per hour ; it is possible that the cost of insurance against fire has risen, but the author has no details. With the present bad coal the consumption is 3.5 kg. per H. P. per hour. If the machine uses more it is in bad condition. The cost of both labour and fuel has risen.

According to the decree of July 31, 1920, the Ministry of Public works fixed the prices of coal as follows: medium quality coal used for threshing, etc., 275 fr. per metric ton at the pit head; English coal 300 fr. per ton on rail at port of importation. With the cost of transport and inevitabl losses on the journey the price at the nearest railway station will be 350 fr. per ton.

Lubricants now cost 5 fr. per kg.

The cost of manual labour is taken at 3 fr. per hour plus 6 % insurance, totalling 3.18 fr. per hour

The following table gives the relative cost per hour before the war and now.

	Before the war	In 1920
	Fr.	Fr.
Fixed Costs: —		
Amortisation, upkeep, repairs	3 40	3.40
Insurance against fire	(Not known)	(Not known)
Supplies:		
Coal	0.54	7.35
Oil, Cottonwaste	0.60	5.00
Increase 10 %	0.11	1.23
Labour: —		
2 men	1.70	6.36
bonus	0.42	1.59
Total . . .	**6.77**	**24 93**
Contractor's profit, 10 %	0 68	2.50
Total . .	**7.45**	**27.43**

M. A. VEZIN, directeur des Services agricoles de Loir-et-Cher, using the following data:— A high consumption of 30 kg. of coal per hour for a 6 H. P. locomotive, a cost of 310 fr. per ton of briquettes at docks, and 350-360 fr. railhead price, 2 men (mechanic and feeder), concludes that for the contractor to earn his living without robbing the farmer, there should be a contractor's charge of 12.50-16 fr. per hour, exclusive of the cost of coal, according to the wear and tear, and time lost in moving away. Coal costs 10.50-10.80 fr. per hour, hence when furnished by the contractor, he may charge from 23-28 fr. per hour.

A 6 H. P thresher requires an average of 600 kilogrammetres per kg. of sheaves yielding 0.33 kg. of grain; assuming that a working hour consists of 50 minutes, the machine can thresh 2 250 kg. of sheaves, yielding 750 kg. of grain per hour.

Given a contractor's price of 25 fr. per hour, the grain costs 3 33 fr. per 100 kg., to which the amount of cost of the labour and teams supplied by the farmer must be added.

According to M. F. LESOURD, threshing wheat in Saône-et-Loire cost before the war from 1.25 fr. to 1.50 fr. per sack of 120 kg. (or 1.04 to 1.25 fr. per 100 kg.) and in 1919 it cost 4.50 to 5.50 fr. per sack (or 3.75 to 4.85 fr. per 100 kg.).

It is desirable to establish co-operative threshing societies, which could buy the machines with advances from the Crédit agricole obtained through la Caisse regional de Crédit mutuel agricole of the district to which they belong.

334 - Cost of Producing Apples in Five Counties in Western New York, 1910-15. — MILLER, G. H., in the *United States Department of Agriculture, Bulletin* No. 851, pp. 1-47, Tables XXV, Figs. 15. Washington, D. C., July 30, 1920.

A record of the relation the orchard bears to additional enterprises such as the cultivation of other fruits and beans, potatoes and hay, with details of the orchard practices followed by the more successful growers, the effect of these practices on yields, the returns derived from different systems of orchard management, and the cost of maintaining orchards under each system. Detailed information is given as to the time required to perform each operation, the necessary equipment, the size of the orchard, the age of the trees, the yield of fruit and other related factors. This investigation was made on 218 apple bearing orchards in the most intensive apple producing area in Western New York, including the counties of Monroe, Niagara, Ontario, Orleans and Wayne. The size of the orchards averaged 35 trees per acre, and the average age was 40 years. The Baldwin variety constituted from 50 to 60 % of the apples grown, and Rhode Island Greening ranks second.

The average investment per acre for the orchards here considered was about $500. This investment was highest in Orleans County and lowest in Ontario. The total equipment investment per farm was $1.158,64 of which about $240 represented the spray outfit. Apart from the latter, the equipment cost $7.75 per acre.

The following list gives the average time required and the cost for the different operations with a crew of one man and two horses: —

Implement	Acres in 10 hours	Cost per acre
Walking plough	1.98	$ 3.00
Roller	12.07	0.45
Disk	7.03	0.84
Spring tooth harrow	9.67	0.57
Spike tooth harrow	11.53	0.48

The most economical means of applying manure was with the spreader. A crew of 1 man and 2 horses with a spreader, applying 9 tons of farmyard manure per acre, covered nearly 2 acres in 20 hours.

The total maintenance cost for the 218 farms was $24.75 per acre or 29 cents per barrel. Deducting a credit for the use of the orchard as pasture, there is left a net cost of $24.04 per acre, about 20 % total net cost of production. The total handling cost was $26.52 per acre or 32 cents per barrel, *i. e.* 10 % total net cost of production.

The following table gives a summary of all costs (218 records, western New York, 1910-15 inclusive).

Item	Five Counties 84.1 barrels Cost		Item	Five Counties 84.1 barrels Cost	
	Per acre	Per barrel		Per acre	Per barrel
Manuring	$ 2.05	$ 0.0244	Picking	$ 12.05	$ 0.1433
Fertilising	0.16	.0019	Shaking, picking up and hauling . . .	0.92	.0109
Pruning	4.85	.0577	Sorting and packing	6.34	.0754
Brush	2.14	.0254	Picking up and haul Culls	1.94	.0231
Ploughing	2.40	.0285	Total net handling cost minus cull credit	12.06	.1434
Other cultivating .	4.26	.0506	Total material cost .	49.07	.5835
Thinning	0.89	.0106	Total fixed cost . .	33.61	.3996
Propping	0.67	.0080	Total material and fixed costs	82.68	.9831
Miscellaneous . . .	0.08	.0009	Total net cost . . .	118.78	1.4124
Sowing cover crop .	0.09	.0011			
Harrowing » .	0.26	.0031			
Mowing	0.10	.0012			
Dormant Spray . .	1.99	.0237			
Summer	4.81	.0572			
Pasture credit . . .	.71	.0084			
Total net maintenance labour cost	24.04	.2859			

The average net cost of production was $7.41 per barrel. By deducting the same, the average net profit was 79 cents per barrel, with an average yield of 84 barrels per acre, or a net profit of $66.36 per acre. If interest on investment ($25.72) is considered as profit rather than as expense, there is a net profit of $92.08 per acre or 18 % on an investment of $514.

The product in this case is the marketable barrelled apple. The byeproducts are the apples sold to the dryer, cannery or cider mill.

PLANT DISEASES

GENERAL INFORMATION

335 - **The Phytopathological Services of Uruguay and the International Phytopathological Convention of Rome.** — Communicated by Dr. E. J. ROVIRA, Delegate of Uruguay.

I have the honour of communicating to my esteemed Colleagues of the Permanent Committee, the information that, by the instrumentality of the Ministry of Foreign Affairs, I have received from the Ministry of Commerce of my country. This communication not only shows the interest taken in the Phytopathological Services by the Government Authorities of Uruguay, but also manifests their entire approval of the work accomplished, and the conclusions reached, by the International Phytopathological Conference held in Rome.

The present constitution of the organisation of the Uruguayan Phytopathological Services completely complies with the formalities declared obligatory by the Convention of Rome in the case of all the contracting States. Through the initiative of Uruguay, an International Phytopathological Conference, similar to that held in Rome, met in Montevideo in May, 1913. It approved three Conventions which, taken together, indicate and establish the same measures as those enforced by the Convention of Rome, and lay similar obligations upon the adherent States.

For this reason, the Ministry of Commerce is of opinion, that there is nothing to hinder Uruguay from notifying her adherence to the Rome Convention.

In accordance with Art. 9, of the International Convention of the « Defensa Agricola » signed at Montevideo, an International Bureau, with headquarters at that town, has been established under the direction of an agricultural expert appointed by the Government of Uruguay. We may therefore conclude that this Bureau will be of great use in establshing international relations with a view to diffusing information respecting the movements of agricultural pests, and the means of their control.

The fact of its existence shows that since the headquarters of this movement in established in S. America, Uruguay should recognise its own obligations and those of the other States united together by the bond of a common aim.

In agreement with this view, and in consequence of the conclusions arrived at by the International Phytopathological Conference of Rome, the

Ministry of Commerce passed the following resolution on September 3, 1914:—

1) All plants, or parts of plants, intended for cultivation, as well as flower-bulbs and cut flowers sent abroad, shall not leave the Country unless they are provided with a certificate stating them to be free from the plant parasites enumerated in the official list of the importing State

2) The General Direction of the "Defensa Agricola" is required to take all the necessary measures for supplying these certificates and obtaining the exporters' declarations in accordance with the stipulations of the International Phytopathological Conference of Rome

3) The products mentioned in Art. 1 shall only be exported from ports authorised by the general regulations dealing with the protection of agriculture.

I much regret that this information did not arrive in time to be incorporated in the interesting report on this subject presented to the last General Assembly by the Hon Delegate of Sweden, but I hope that it will nevertheless be received with satisfaction by the Permanent Committee.

As regards the definitive adherence of Uruguay to the Convention of Rome, I am awaiting the instruction, of my Government.

DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS.

336 – **The "Cignarellone" Wheat of Molise, Italy, Resistant to Rust, Lodging and Grain Shedding.** — See No 283 of this *Review*

337 – **"Mogarbia" Wheat of Cyrenaica, Resistant to Lodging and Immune to Smut.** — See No 252 of this *Review*

338 – **Resistance of Different Varieties of Cabbage to *Fusarium conglutinans* Wollenw. in the United States.** — JONES, L R, WALKER, J C, and TISDALE, W B, in *Agricultural Experiment Station of the University of Wisconsin Research Bulletin*, No 48, pp 3-34, tables 5 + figs 10 Madison, November, 1920

The general facts regarding the nature of Cabbage Yellows (*Fusarium conglutinans* Wollenw), and the results obtained with various control measures and with different varieties of cabbage resistant to disease in 1915, have already been described (1). Since then, work has been continued with new and advantageous results here notified by the authors, with special reference to the resistant Wisconsin Hollander strain selected from the commercial Hollander or Danish Ball Head, used for winter storage purposes (1) from which further selection was made and a new resistant strain secured which combines earlier maturity with a rounded head and shorter stem, and distributed under the name of Early Wisconsin Hollander.

---

(1) See *R*, March, 1916, No 355 and *R*, May, 1918, No. 594 (*Ed*)

In order to meet the needs of the Kraut industry, resistant strains have been selected from two of the leading commercial Kraut varieties, Brunswick and All Seasons. The so-called Wisconsin Brunswick XI-7-1 strain so obtained, proved the best of those tested in 1918 and 1919 but although the needs of Wisconsin growers in certain districts seemed fairly well met by the Wisconsin Hollanders and Wisconsin Brunswick, these 2 varieties did not adequately meet the national situation The resistant strains, however, obtained by selection from the All Seasons hybrid strain showed only 2 % of *Fusarium* infection, and the selfed strains scarcely more. This was a distinctly better showing than was made in the parallel trials the same season with the 2 above mentioned selections.

The following selections of other resistant varieties are recommended for further propagation and selection. Maryland Flat Dutch, All Head Early, Glory of Enkhuizen, Copenhagen Market and Late Flat Dutch. Attention is drawn to the fact that *Fusarium conglutinans* is often confused by growers with the bacterial black rot (*Bacterium campestre*), and that the selected strains mentioned have not proved to be especially resistant to this nor to the other common cabbage diseases such as *Phoma brassicae* and club root (*Plasmodiophora brassicae*) In all cases the degree of resistance to *Fusarium* shown by these strains is relative, not absolute. The seedlings are less resistant than the plants after transplanting. In consideration of the fact that high soil temperature favours the disease and low temperature inhibits it, the best results are obtained under Wisconsin climatic conditions by starting even the resistant strains in a non-infested seed bed to avoid possible seedling infection These strains are then sufficiently resistant after transplanting to give a commercially successful crop even on badly diseased soil. In order that the present standards may be effectually maintained, seed must be employed secured from plants carefully selected for resistance and type from recognised infested fields. The authors consider that through further selection, resistant strains suited to any localised conditions could be secured.

339 – **Behaviour of the "Teroldigo" and "Negrara" Vine varieties of Trentino, Italy, as Regards Diseases and Pests.** — See No 302 of this *Review*

340 – **The Part Played By Copper in Anticryptogamic Mixtures.** — VILLEDIEU, VIALA SAGNIER, H and GERVAIS, P, in the *Comptes rendus des Seances de l'Académie d'Agriculture de France*, Vol. VI, No. 31 (October 27, 1920), pp 762-766 and 754-756. Paris, 1920.

It occurred to M. and Mme. G VILLEDIEU that it would be interesting to determine whether copper is really an essential ingredient of anticryptogamic mixtures, or in other words, whether metallic copper is the substance which destroys the zoospores of the "mildew" of the vine. They were of opinion, that it was necessary to test this supposed toxic action, as GALIPPE and his successors have shown that metallic copper and most cupric compounds, with the exception of certain very acid salts such as the sulphate or chloride of copper, are innocuous to nearly all forms of life other than cryptogams.

M. and Mme. VILLEDIEU first proved the truth of the theory of the dissolution of cupric mixtures by rain-water. They had already demonstrated, by previous experiments, the fallacy of the statement that milk of lime acting upon a solution of copper sulphate gives rise to the formation of copper hydrate, which is transformed in the air into basic copper carbonate (hydrocarbonate) (1).

Subsequent experiments made with rain-water containing ammonia or carbon dioxide, or both substances in varying proportions, as well as experiments on basic sulphate or basic carbonate of copper, both pure and mixed with lime, sodium carbonate, calcium carbonate, or calcium sulphate have led to the conclusion that:—

1) With normal rainwater, it is impossible to dissolve traces of copper equal to 1 millionth part.

2) It is necessary to increase a hundredfold each of the gases present in rainwater, in order to obtain solutions containing a millionth part of copper.

The idea, hitherto accepted without any proof, that cupric deposits are dissolved by rain-water, seemed so unlikely to M. and Mme. VILLEDIEU that they investigated the cause of the effect produced by anticryptogamic mixtures. They turned to account in the laboratory the experimental results of J. PERRAUD, who replaced sulphate of copper by the sulphate of nickel or cadmium with equal success, in mixtures used for the control of vine "mildew." They studied the effect of copper and its compounds upon moulds in general, and succeeded in growing these fungi in media containing 2, 5, and even 10 % of ammoniacal citrate of copper; *Penicillium glaucum* will even live on a saturated solution of this salt.

It may be concluded from the results of these experiments, that the contact of a strong mineral acid, such as sulphuric acid, or of a mineral base or oxide, prevents the development of the fungus spores by altering the chemical composition of the contents of the initial cell, which has little power of self-defence. It also seems possible, in the case of vine mildew and other fungi, to attribute the action of the copper sulphate to the free sulphuric acid it liberates in solution, and to regard the effect of the hydrocarbonate as due to its basic nature.

In the same way, we may explain the more powerful effect of really alkaline mixture, where the alkalinity of the lime is added to that of the cupric base.

Finally, M. and Mme. VILLEDIEU confirmed their results by another experiment made directly upon the Peronospora, *Phytophthora infestans*. They introduced into culture tubes with solid media pieces of healthy potato (their freedom from disease being shown by control pieces) that had been soaked for a period varying from 6 hours to 4 days in 1 per 1000, 1 per 10.000, and 1 per 100.000 solutions of ammoniacal copper. These slices of potato, while dripping with the cupric solution, were sown with zoosporangia of *Phytophthora* taken from similar solution. After 4 or 5 days, all of them produced the conidiophores (zoosporangiophores) and zoosporangia characteristic of potato " mildew."

(1) See *C. R. des Séances de l'Académie des Sciences*, Vol. CLXXI, p. 360. Meeting of Aug. 9, 1920.

As regards, vine " mildew," M. and Mme. VILLEDIEU, in 1920, introduced into vine stocks a sufficient amount of ammoniacal citrate of copper to allow of the presence of the copper being detected in the sap and leaves of the plants thus treated. These leaves were, however, attacked by " mildew." According to these investigators, copper is thus no more toxic to the fructifications of *Peronosporaceae* than to other fungi. It would hence appear possible *a priori* to replace it in anticryptogamic mixtures by another and more common metal.

The results announced by M. and Mme. VILLEDIEU led MM. VIALA, H. SAGNIER, and P. GERVAIS to make the following remarks: —

M. VIALA considers that the conclusion arrived at by M. and Mme. VILLEDIEU is not exact from the practical standpoint. It again leaves the question undecided whether it is really the copper that affects the " mildew " of the vine, or whether it is the acid or base present in the mixture. If however, the laboratory experiments of these two workers were confirmed, it would greatly reduce the expense of the control of vine mildew.

M. H. SAGNIER suggests that as these researches have only taken the form of laboratory experiments, it would be advisable to counsel vinegrowers to continue the treatment which has hitherto proved efficacious, and to wait until the new theory has been tested practically.

M. P. GERVAIS commends M. SAGNIER's prudent advice to vinegrowers, and remarks that when it has been proved by numerous experiments that copper has no effect upon mildew, some other method of treatment can be adopted, especially if it be more economical, but that the question is at present in the laboratory experiment stage. As long as it has not passed into practice, the only wise course is to continue to use the means of protection that have been recognised for a great number of years as being effective.

341 - **Diseases of Wheat in Parana, Brazil.** — See No. 285 of this *Review*.

342 - ***Septogloeum Arachidis*, Leaf Spot of the Peanut in South Africa.** — VAN DER BIJL, P. A., in *Union of South Africa, Journal of the Department of Agriculture*, Vol I, No. 6, pp. 528-530, figs. 2. Pretoria, Sept. 1920.

In South Africa and especially along the coastal region of Natal, the peanut is seriously attacked by *Septogloeum Arachidis* Rac. The disease shows itself as black, circular to irregular spots or flecks on leaves and stems; the attacked leaves die early and shrivel up or fall.

This leaf spot has also been notified in Transvaal, British East Africa and in countries other than Africa

Since the damage caused at times by the fungus is considerable, it is recommended that the material from diseased fields be burnt or else deeply ploughed into the ground.

Crop rotation should be resorted to in old lands. In regions where the trouble is known to occur a fungicide sprayed early before there are signs of disease is advised. If this spray will not benefit plants already badly diseased, it is however, even in these cases a distinct advantage as it will kill the spores of the fungus through which the disease is disseminated.

343 - **Anaerobic Bacteria and Gummosis of the Walnut in France.** — DUFRENOY, J., in the *Comptes rendus des Séances de la Société de Biologie*, Vol. LXXXIV, No. 3, pp. 132-133. Paris, 1921.

Of recent years, a disease has attacked walnut trees of all ages in the central Massif and in the Pyrenees ; patches of dead trees are seen surrounded by dying ones, and the malady is extending to the walnut plantations. At Nuces (Aveyron), where the walnut has been grown commercially from very ancient times, the disease shows itself on the trees at the edge of the patches, by a withering of the top branches; cracks appear in the trunks, the bark becomes dry at the junction of trunk and root, and root-rot sets in. The first sign of root-rot is a black discoloration of the extremities from which the cortex is easily detached. Mycelial filaments penetrate into the portions of the roots that are not discoloured filling the cells of the medullary rays with brown or greyish swollen bodies (arthrospores or conidia ?).

Sections of the collar or of the roots reveal (disseminated through the cambium, the wood, and especially the pericycle) numerous cells massed on the brown edges of the root cankers, and filled with yellowishbrown gum. Owing to the destruction of the pectic substance of the middle lamella, the cells become separated at the corners, and the membrane turns brown. Fragments of roots affected with gummosis, but not discoloured, after being sterilised and split were placed on peptonised gelatin containing glucose, or enclosed in it. No change occurred in the parts exposed to the air, but from those that were protected from its action, there extended through the gelatin, right down to the bottom of the tubes, grey colonies of short-rod shaped bacteria enclosed in a mucilaginous zoogloea, but which became mobile in water.

It is impossible to be certain whether these anaerobic bacteria are responsible for the death of the walnut-trees, or if, as COMES and SAVASTANO maintained in the case of the bacteria found by them, they are merely secondary parasites that have penetrated into the trees through lesions due to bad weather (cankers caused by frost cracks).

344 - **Diseases and Pest of the Vines in the State of Rio Grande do Sul, Brazil.** — Se No. 301 of this *Review*.

345 - ***Phomopsis Pseudotsugae*** **Deuteromycete Injurious to** ***Pseudotsugae Douglasii*, in England** — ALCOCK, N. L., in *The Gardener's Chronicle*, Vol. LXIX, No 1778, p. 45, figs 1. Jan. 22, 1921

During the summer and autumn of 1920, plantations of Douglas Fir (*Pseudotsuga Douglasii*) were attacked by *Phomopsis Pseudotsugae* (1) in several English localities; the characteristics associated with the attack were similar to those previously observed in Scotland.

The disease in causing serious loss among the English plantations. In one case in Hampshire in 1919, over 20 % of the young leaders are reported to have been killed, which will seriously affect the future shapeliness and value of the trees. In an adjoining plantation with trees of about 8 years old, considerable numbers of stems and branches are affected.

At Bagshot (Surrey) in the nursery at Ripley, the disease has attacked and injured a considerable number of transplants, *i. e.* 4 year old plants. At Swinley (Berkshire) and in other nurseries, the disease has attacked the leader or the young branches of a considerable number of plants. It has been found at Midhurst (Sussex), and is probably widespread, and is evidently a serious pest as regards young plantations of *P Douglasii.*

346 - ***Botrytis Douglasii*, Hyphomycete Injurious to *Pseudotsuga Douglasii*, Newly Recorded in Scotland.** — WILSON, M., in *Transactions of the Royal Scottish Arboricultural Society*, Vol. XXXIV, Pt. 2, p. 223. Edinburgh, Nov 1920.

Diseased specimens of the Douglas Fir (*Pseudotsuga Douglasii*) were collected in Perthshire and were found to be attacked by *Botrytis Douglasii*; a disease which is widespread on the Continent, but which up to the present does not appear to have been recorded in Scotland. The specimens which were taken from the lateral branches of a tree about 18 years old, have a very characteristic appearance. The terminal portion of the shoot is brown and withered, and the stem, as a result of the attack of the fungus, loses its rigidity and bends over a few inches behind the apex, from 4 to 6 in., of the branch are killed. The brown leaves near the apex usually persist, but those further back fall, and the bent portion of the stem is generally bare. The delicate grey mycelium of the fungus, which can be seen with a lens, produces during the summer, numerous conidia, which germinate at once in water and infect the young developing shoots and needles. In the autumn small black sclerotia are produced, and burst through the bark often under the old bud scales. These sclerotia, if kept in a damp atmosphere, produce numerous branched conidiophores which bear large numbers of conidia.

It is probable that *B. Douglasii* is identical with the common saprophytic mould *B. cinerea*

Several investigators have shown that this saprophyte is capable of growing as a parasite on silver fir, larch, spruce as well as *Ps. Douglasii*, and it has been notified on the larch and Scotch pine (*Pinus sylvestris*) in England.

---

Under damp conditions, it spreads rapidly and may cause considerable damage.

INJURIOUS INSECTS AND OTHER LOWER ANIMALS

347 - **New Aphids Discovered in Italy.** — DEL GUERCIO, G., in *Redia*, Vol. XIV, Parts 1 and 2, pp. 107-136, 1 plate. Florence, February 10, 1921.

Observations on the morphology and systematic position of 9 species and 2 genera of aphids that the author describes as new to science. Together with the new species, the author mentions two others already known to science, and which he places in the genus *Eucarazzia*, that he has just created, beside those insects he describes for the first time:—

1) *Rhopalosiphum trilineatum* n. sp., collected from chrysanthemums in the Val di Nievole, and the Valley of Montecatini.

2) *Anuraphis fasciatus* n. sp., found on lucerne in the above-mentioned localities.

3) *Anuriella dorsolineata* n. gen. and n. sp., also found in the above places.

4) *Pentaphis viridescens* n. sp., on the rhizomes of couchgrass (*Agropyrum repens*) in the Cascine at Florence.

5) *Pentaphis apuliae* n. sp., found in the meadows of St. Cecilia (Foggia)

6) *Tetraneura reticulata* n. sp., found under the same circumstances.

7) *T. flavescens* n. sp., on wild barley in the neighbourhood of Florence.

8) *T. agnesii* n. sp., on the flowers of the olive in the Province of Porto-Maurizio.

9) *Eucarazzia picta* n. gen. and n. sp., on the leaves of field calamint (*C. Acinos*) at Acicastello (Catania).

10) *E. calthae* (Koch) (*Rhopalosiphum calthae* Koch).

11) *E. najadum* (Koch) (*Rh. najadum* Koch).

348 - **New Weevils Injurious to Various Cultivated Plants in Africa, Asia and Oceania.** — MARSHALL, G. A. K., in *Bulletin of Entomological Research*, Vol. XI, Pt. 3, pp. 271-278, pl. 1. London, Dec. 1920.

Description of the following Curculonideae:

1) *Tanymecus destructor* n. sp., injurious to maize, and sweet potato in S. Rhodesia;

2) *T. agricola*, injurious to maize in S. Rhodesia;

3) *Isaniris ater*, occurs very commonly on trees of the genus *Brachystegia*, and also attacks various cultivated plants, including citrons, in S. Rhodesia and Nyasaland.

4) *Systates exaptus*, commonly found on different herbaceous plants; appreciable injury caused to young maize plants in S. Rhodesia;

5) *S. chirindensis*, found on leaves of coffee bushes in S. Rhodesia;

6) *Calandra shoreae*, attacks seeds of the sal tree (*Shorea robusta*) as well as those of *Dipterocarpus turbinatus*, in Mauritius and various parts of India;

7) *C. glandium*, bred from acorns of *Quercus incana* and *Q. dilitata* in various parts of India;

8) *Stenommatus musae*, found breeding in the corm of a banana plant in the Hawaiian Islands.

349 - **The Hymenopteron *Opius fletcheri* as a Parasite of the Melon Fly (*Bactrocera cucurbitae*) a Dipteron Injurious to Various Cultivated Cucurbitaceae, in the Hawaiian Islands.** — WILLARD, H F, in *Journal of Agricultural Research*, Vol XX, No 6, pp 423-438, figs 13 Washington D C, Dec 15, 1920.

The braconid parasite *Opius fletcheri* Silvestri was introduced into the Hawaiian Islands from India in May, 1916 to destroy the Melonfly (*Bactrocera cucurbitae* Coquillet) which had been causing great losses to vegetable growers of the islands. *B. cucurbitae* is the only host which *O. fletcheri* attacks freely under field conditions, although the hymenopteron can be bred freely in the laboratory from the Mediterranean fruit fly (*Ceratitis capitata* Wiedemann). However, from many thousands of *C. capitata*, secured from fruits collected in the field, only four adult *O. fletcheri* have been reared.

The author gives a detailed description both morphological and biological of this hymenopteron. Since its introduction into the Hawaiian Islands it has become firmly established on all the larger islands of the group, and has shown itself capable or reducing the number of *B. cucurbitae* by at least 25 %, even when the host larvae are developing in fruits the size and nature of which makes parasitism difficult In a location, where fruits and conditions are most favourable to its reproduction, it has reduced the flies so greatly that they have almost ceased to be a pest.

350 - **Poultry as a Means of Checking Insect Pests in Fruit Orchards.**— See No. 325 of this *Review*.

351 - **Chloropicrin as an Insecticide for the Destruction of Seed Parasites.**— See No. 265 of this *Review*

352 - ***Alcides leucogrammus*, Coleopteron Injurious to the French Bean and to *Vigna Catjang* in Rhodesia.** — JACK, R. W., in *The Rhodesia Agricultural Journal*, Vol XVII, No 5, pp 452-455, pl 2. Salisbury, Oct 1920.

Since 1913, where it was observed in a garden near Old Umtali, the Curculionidae *Alcides leucogrammus* Erich (Bean Stem Weevil) has appeared annually on the experimental plots at Salisbury, and has been observed on farms in different parts of Mashonaland.

It has only been found attacking French beans and Cow peas (*Vigna Catjang*).

The beetles feed mainly upon the stems and branches of the host plants in which they cut longitudinal grooves. The eggs are laid in cavities at the base of the stems; these are first prepared by means of the mouth parts. The larva feeds on the tissues at the base of the stem, several commonly being found on one plant, and considerable swelling, often accompanied by the formation of callus, results. When only one larva is present, it is often entirely enclosed in the swollen stem and callus may not form to any great extent; but when, as is often the case, several are present, some are only partially buried in the stem and much callus may be present.

A plant may apparently carry one grub without actually dying, but its growth and production are seriously interfered with. Many plants are killed outright and others become yellow, drop their leaves and die more slowly.

After describing the stages and habits of the weevil, the author states that no parasites have been bred from the grubs. Observations in the field, have, however, indicated considerable destruction by natural enemies, of the pupae or resting adults, and probably also the larvae. The driver ant *Dorylus helvolus* appears to be the chief enemy in this respect.

All plants subject to attack should be pulled up and burnt.

353 - ***Earias insulana*, var. *anthrophilana*, a Macrolepidopteron Parasitic on the Cotton Plant and on "Gombo" *(Hibiscus esculentus)* in Cyrenaica.** — ZANON, V, in the *Rivista di Agricoltura*, Year XXVI, Nos. 1 and 2, pp. 5 and 23-24. Parma, 1921.

In 1919, a regular invasion of the macrolepidopteron *Earias insulana* var. *anthophilana* was reported from Benghasi, where it had attacked *Hibiscus esculentus*. In preceding years, this insect had also been found in Benghasi, and had done a certain amount of injury to cotton (*Gossypium barbadense*).

In both cases, the caterpillars injured the fruits more or less, so that the crop was considerably damaged.

It is certain that, in Cyrenaica, there are two generations of *Earias insulana* on the two host plants: if the season is good there is a third, but this confines itself to the *Hibiscus*.

As a control measure, it has been advised, in Upper Egypt, to keep all Malvaceae as far as possible from the cotton plantations. The author, on the other hand, suggests that *H. esculentus* should be sown very early near the fields of cotton, for since its fruits are much tenderer and earlier than those of the latter plant, it would attract the first generation of insects. After the moths have laid their eggs, all the "gombo" fruits should be gathered, and the plants pulled up, before the insects are able to assume their adult form.

354 - **The Tobacco Slug (*Lema bilineata*) in South Africa.** — VAN DER MERWE, C P., in *Union of South Africa, Journal of the Department of Agriculture*, Vol. II, No. 1, pp. 28-38, figs. 3. Pretoria, Jan 1921.

Since 1911, the slug *Lema bilineata* Germar, has been observed several times in Natal, also in the Orange Free State, in the Cape Province, and in Swaziland. Its native home appears to be in South America and it is likely now to become a serious pest from the commercial standpoint as regards tobacco cultivation in South Africa.

This beetle is popularly termed tobacco leaf slug and has the habit of attacking the tobacco in the seed beds, field, curing sheds and even in the bales.

In the field, the lower side of the leaves are attacked by the larvae, in close masses. Later, they separate and eat large ragged holes in the leaf. If many larvae are present on a leaf, in a short time only the midrib and a few large side ribs will be left. In the seedbeds, the mode of attack is similar; the central plants which are close together being attacked first. In some cases, half the plants have been destroyed, dozens of larvae being found on every leaf, and in other places, the plants, both in the seedbeds and in the fields, were completely destroyed. The tobacco is only attacked in the curing sheds and in the bales when still green. In the Piet Relief District, the custom is to cut the whole plant and hang it up in the shed to dry, which demands more than a month, and there is, therefore, time for larvae to develop to maturity. The damage done in sheds is very great, and perhaps relatively greater than in the field, as the insects are better protected from natural enemies and unfavourable climatic conditions. Such damage can be prevented by other methods of drying, but it is thought the damage in the shed will be trifling if the pest is properly controlled in the field.

The author gives a detailed morphological and biological description of the insect and its various stages and habits.

In Durban the possible maximum number of generations in the year appears to be eight. Besides on tobacco, the slugs have been observed to feed on *Physalis* spp. *Nicandria physaloides, Datura Stramonium* and *D. Tatula*. At Cedara, it occurs on potatoes. The adults appear to have the same food plants as the larvae, but they are not so voracious and do not do so much damage.

As regards means of distribution, the greatest danger appears to lie in transported bales of tobacco. According to certain reports the pest is greatly favoured by wet weather and moist soil.

Amongst the natural enemies, may be mentioned, in order of importance, the ants *Pheidole punctulata* and *Myrmicaria eumenoides;* and amongst the Rhynchotes different species of the fam. Reduvidae have been seen attacking both beetles and slugs.

A spider has been observed carrying off both young larvae and adults of *L. bilineata*. Chickens and turkeys willingly eat the larvae. Cocoons have been found eaten out, apparently by a rat or a mouse.

Several control measures have been tried with success, *e. g.* hand crushing; spraying with arsenate of lead (in paste form 2 lb. of paste in 50 gall of water and in dry powder 1lb. in 25 gall. of water; the powder is generally preferable to the paste); dusting with arsenate of lead powder; dipping young tobacco plants before setting out in the field in arsenate of lead and water of the strength recommended for spraying.

355 - **Tamarind Pod-Borer, *Sitophilus linearis* in the United States.** — COTTON, R. T, in *Journal of Agricultural Research*, Vol. XX, No. 6, pp. 439-446; pl. 1. Washington, D. C., Dec. 15, 1920.

The literature of North American entomology contains occasional reference to the curculionid beetle *Sitophilus linearis* (Herbst), but nothing definite has been published regarding the biology of this weevil or the extent of its distribution in the United States.

The tamarind pod-borer was described in 1797 from specimens obtained from the West Indies, where the weevil had been introduced with its food plant, the tamarind. It is undoubtedly indigenous to India, but has now spread to all places where the tamarind is grown. In 1892 CASEY noted the occurrence of *S. linearis* in North America, but in 1895 CHITTENDEN stated that in his opinion *S. linearis* should not be inserted in the North American fauna list until it could be ascertained that the species actually bred in some plant within the faunal limits. Up to the present, records of its occurrence in the United States refer to occasional specimens picked up in the Southern Atlantic and Gulf States, which had undoubtedly been imported in shipments of tamarind pods. The author has found it to be exceedingly abundant in southern Florida, where the tamarind is now grown , there is, therefore, no longer any doubt that it is well installed within the North American faunal limits.

In 1916, this species was notified as causing considerable damage to the pods of the tamarind in Jamaica and even in India. The weevil is now known to occur in the United States, India, Brazil, Mexico, Ecuador, Jamaica, Montserrat, St. Bartholomew, Cuba and Costa Rica It occurs, undoubtedly, wherever the tamarind is grown.

The attack is confined entirely to the seed pods ; the adult weevils feed little, but the larvae bore in the seeds or beans and reduce them to powder. The entire crop is frequently completely destroyed unless promptly harvested and protected.

Descriptive notes are given of the egg, mature larva, larval instars and of the pupa and of the life history, and biology according to observations made in Florida.

No parasites have up till now been reared from any of the stages of *S. linearis*. Larval and pupal stages were attacked and killed in the laboratory by a predacious mite, *Pediculoides ventricosus* Newport. It seems very doubtful, however, that this mite would be able to penetrate to the larval burrows under field conditions.

356 – ***Rhabdopterus picipes*, Coleoptera Injurious to the Apple in the New York State.** — SAWYER, W. S, in *The Canadian Entomologist*, Vol. LII, No 12, p. 265, pl. 1. London, Dec. 1920

On June 28, 1920, in an orchard near Sodus (New York), large numbers of *Rhabdopterus picipes* Oliv. were found feeding on apples, especially variety Grimes Golden, eating out a shallow, irregular, hieroglyphic like channel on the surface. About 75 % of the apples were injured in this manner.

The beetles continued feeding until the middle of July, after which time they were found feeding on the foliage of *Vitis hederacea*, *Rumex* and wild strawberry. Apple leaves were not attacked.

When feeding on the foliage, holes were made similar to the channels on the fruits ; in some cases riddling the leaves so that only the veins remained. About August 1, the beetles disappeared.

In 1920, the work of the insect seemed to be confined to the vicinity of Sodus and Savannah (New York). In the latter place it was most abundant on the foliage of wild strawberry and *Rumex*. The damage to the apples in this locality was not great.

Attempts to kill the beetles by spraying with arsenate of lead were not successful.

INJURIOUS VERTEBRATES

357 - **Toxicity of Barium Carbonate to Rats.** — SCHWARTZE, E. W. (Pharmacological Laboratory), in *United States Department of Agriculture, Bulletin* No 915, pp. 1-11, tables 10, bibliogr of 20 works Washington, D. C., Nov. 12, 1920.

A series of experiments on the toxicity of various substances to rats, and their suitability as poisons was undertaken in 1918, at the request of the Bureau of Biological Survey of the United States Department of Agriculture, for the purpose of obtaining toxological data for use in connection with the rat-extermination work in the zone of occupation of the American Expeditionary Forces. These studies have been continued because of their importance to agricultural economics as well as to the public health.

In the experiments here reported the brown rat was used as often as practicable, and the domesticated white strain was employed for obtaining accurate food-intake data, and for testing the relative efficiency of different percentages of barium carbonate in the bait. The barium chloride administered was the ordinary crystalised salt ($Ba\ Cl_2 . 2\ H_2O$). The carbonate, which was of high purity and free from soluble chloride, was always used in the form of fine powder, having been passed through a 100 mesh sieve.

The subcutaneous lethal dose of barium chloride was from 45 to 89 mg. per kilo and the oral lethal dose from 355 to 535 mg. per kilo. The results of the 2 sets of experiments, given in the order of the barium intake per kilo, are in general agreement, the efficient lethal dose of barium carbonate being from 630 to 750 mg. per kilo. On the basis of the barium content, the carbonate is about $^2/_3$ as active as the chloride.

The average intake of food, both poisoned and unpoisoned, by hungry white rats used in these tests was $^1/_{200}$ of their body weight.

An efficient concentration of barium carbonate in the rat bait was 20 %. With this percentage, a rat is required to eat only $^1/_3$ or $^3/_8$ of a meal of average size, or $^1/_{320}$ to $^1/_{266}$ of its own weight, in order to secure the ingestion of a lethal amount. With this concentration, many of the rats die within the first 24 hours, the chief factor being the consumption of an amount larger than the minimum efficient lethal dose. From the results of both the pharmacological and the feeding tests, it would not seem advisable always to expect 100 % mortality from the administration of barium carbonate to rats in proper amounts

GENERAL INFORMATION

358 - **Agriculture in Julian Venetia** (1). — TAMARO, D., in the *Giornale di Agricoltura della Domenica*, Year XXX, No. 43, p. 137. Piacenza, Oct. 24, 1920.

Agriculture is practised in Julian Venetia under natural conditions that are common to a number of regions in Italy. The conditions of the coastal zones differ but little from those of Liguria, except that rainfall is less abundant and not so well distributed. The coast from Trieste to Salvore is swept more often by the "bora", a strong N-E-E wind. The myrtle flourishes at Miramare: the coastal hills are covered with olive trees as far as Salvore; laurels abound at Abbazia, and palms flourish in the Brioni islands and at Lupino. This favoured zone of Julian Venetia represents a fifth of the cultivated area.

Between Gorizia and the sea, *i. e.*, in Eastern Friouli (62,000 hectares in area), where the climate is temperate, grain is cultivated, in regular rotation with artificial meadows and hoed crops. Other alluvial soils are found in Istria along the banks of various rivers, and these soils, as at Capodistria, Isola, and Pirano, are covered with vines, fruit trees, and vegetable gardens. The land around the Arsa and Orvieto rivers require improvement to stamp out malaria. These improvements would enable the whole of Istria to be given an adequate supply of drinking and irrigation water.

---

(1) See: DOMENICO TAMARO. L'Agricoltura della Venezia Giulia. Casalmonferrato, 1920. GIOTTO DAINELLI. La Dalmazia. Novare, Ist. Geogr. de Agostini, 1918 (*Ed.*)

[Abstract No. 358]

Seventy per cent. of the cultivated land consists of "terre rosse" (red earth), *i, e.*, the Carso zone (566,000 hectares) comprising the islands of Carnaro, and reappearing between Fiume and Fianona. At an altitude of 1000 metres this zone extends in a northwesterly direction, occuping most of Istria, Trieste, Postumia, Longatico and, as it nears the Isonzo, slowly drops, occuping part of the districts of Gorizia, Gradisca, and Tolmino, and ends by mingling with jurassic and triassic formations.

The Carso consists of plateaux and hilly, undulating terraces, with soils derived from eocene formations collected in deep pockets and forming veritable oases covered with luxuriant vegetation, which is often dried up in summer. In Istria, at an altitude of 350 metres, the olive and other fruit trees are grown in these soils, more or less associated with cereal crops which, in their turn are grown on fallow land in order to conserve soil moisture. Above this altitude, meadows and woods predominate, with vast areas under cereals and potatoes.

The productive agricultural land of Julian Venetia covers about 800.000 hectares and represents 94 % of the total area. In 1913, the distribution of the various crops was as follows:

250 000 hectares of pasture crop value 55 200 000 *lire ;*
222 000 » of wood crop value 11 100 000 *lire ;*
120 000 » of plough and hand-worked land, crop value 78 800 000 *lire ;*
100 000 » of meadow and alpine pastures, crop value 23 200 000 *lire ;*
55 000 » of vineyards, crop value 31 700 000 *lire ;*
53 000 » comprising the districts of Postumia, Longatico, and Idria.

The agricultural produce was thus worth 200 million *lire*, or 267 *lire* per hectare.

The number of head of livestock in 1913 was 140 000 cattle, 250 000 sheep and goats, 60 000 pigs, and 10 500 horses. These animals gave a weight of 5 quintals per hectare, 6 quintals per hectare in Istria, and 5 in Gorizia. The fodder obtained from rotation meadows, permanent meadows, and from pastures, including forest pastures, gave, as hay, 10.2 million quintals. The ratio between tilled and meadow and pasture land is 1 : 3.5, and corresponds to that of the best agricultural countries; thus there should be a very high unit yield of grain, if, especially in Istria, it were not for the arid soils in the Carso, as these receive abundant rain in autumn and winter, but very little in summer.

The Istrian cattle are of the podolian type improved by crossing with the romagnol breed, whereas on the platean of Gorizia, the Simmenthal breed has been introduced. The mountainous zone of Gorizia possesses the alpine type, which gives good milch cows. The number of sheep is very great, especially in Istria, for the poor Carsic pastures can only be utilised by sheep. In Istria the goats have providentially disappeared except amongst the rocky mountain tops.

The forest produce is valued at a low figure, because no proper management has been applied save in the forests of Gorizia, Postumia, Longatico, and in certain other centres, such as Montona, in Istria The war wrecked most of the reforestation which had been effected with such difficulty on the Triestine Carso and reconstitution is urgently required. The average wheat crop is 10 quintals per hectare with a minumum of 8 quintals in Istria, and a maximum of 14 quintals in Gorizia. In Istria, maize yields 9.5 quintals per hectare, and Gorizia 22.6 quintals. The same difference in unit yield is seen between the two provinces for all the other types of crops, as is shown in the following table :

Average unit production of herbaceous crops in the provinces of Istria and Gorizia.

Plant	Total area cultivated in the two provinces	Total production in the two provinces	Average production in cwt per hectare	
			Istria	Gorizia
	Hectares	Quintals		
Wheat, Barley, Oats, Rye .	32 550	288 000	8	14
Maize	93 973	91 000	9 5	22.6
Potatoes.	13 657	1 214 000	55	141
Pulse	4 354	34 000	7.4	10
Rotation hay	12 527	680 000	45	61

Istria suffers from drought to such an extent that even drinking water is scarce, and it is for this reason that rotation meadows are too little developed and fallow crops predominate.

But, in Istria there are 46 434 hectares under vines either alone or grown in conjunction with the olive tree and with cereals. In the neighbourhood of Trieste, the vine is not only cultivated with the olive but with other fruit trees as well as vegetables. The cultivation, associated or separate, of vegetables and fruit trees is equally intensive around Gorizia, whilst, in the Friouli plain, the crops are grown in fields planted with lines of mulberry trees, where three and four year rotations, are carried out and where there is excellent pasturage in the Alps. Under the old régime, more attention was paid to forestry than to agriculture, but less than in the other countries which formed the former Austrian Empire. Agriculture in this region was directed by a central inspectorat with head quarters at Trieste, and on which the chair of agriculture of each district was dependant. In Istria, however, a provincial law was passed instituting an Agricultural Council, whose president was nominated by the Government. The Province of Gorizia had an agricultural inspector nominated by the province who is still in office.

359 - **Agricultural Possibilities in Ceylon.** — *The Tropical Agriculturist*, vol. LVI, No. 1 pp. 1-2. Peradeniya, Ceylon, Jan. 1921.

The possibilities of establishing and extending other industries in Ceylon is at present a subject much discussed. Although tea, rubber, and coconuts form the bulk of exports, these are, however, other export industries that occupy comparatively important positions in certain areas of this colony.

Experiments carried out several years ago at Hakgala and at Peradeniya demonstrated the possibilities of cultivating camphor on higher elevations. Considerable areas of this crop were covered, but the greater portion has since been cut out and replaced by tea or timber. Now that the price for tea has fallen and the price for camphor has risen and according to information from reliable sources, is likely to remain high the cultivation of this product is worthy of reconsideration.

Sisal (*Agave* sp.) has been demonstrated at the Anuradhapura Experiment Station to be a crop with possibilities for the dry zone, and a syndicate has undertaken the cultivation of this fibre upon estate lines. There are good prospects for this fibre and for *Furcraea* as a crop for the small cultivator.

The most promising results with regard to cotton cultivation have been obtained from certain areas of the Southern Province, and provision is being made for a trial upon a commercial scale of various varieties; and for the inauguration of a purchase scheme for peasant grown cotton.

The *robusta* types of coffee are being extended. Plants of known percentage for selected seed bearers in Java have been secured during the past few years and are now coming into bearing

Trials are being made at Anuradhapura with oil palms introduced from West Africa. It is considered possible that this oil producing crop may offer favourable prospects for cultivation upon lands not suited for coconuts.

Other crops that deserve the closest investigation in Ceylon are sugar and limes. The former can be grown with profit and with careful cultivation, high yields can be secured. The establishment of sugar cane cultivation upon estate scale is a necessity under the present conditions, although it may also prove a profitable proceeding for small holders who supply canes to a central factory. Limes grow and yield excellently in many parts of the colony, and it has already been demonstrated in the West Indies that this crop is a profitable one.

There are many additional crops which can be added to those at present under cultivation. Definite experiments are, however, essential at the start, and the establishment of an increased number of experiment stations under trained supervision is necessary.

360 - **Tsetse-Flies in French West Africa.** — ROUBARD, E (Head of the Laboratory of the Pasteur Institute in Paris), in the *Bulletin du Comité d'Etudes historiques et scientifiques de l'Afrique Occidentale française*, No. 4, pp. 257-300, 7 fig. + 1 map. Paris, July-September, 1920.

The author studies successively:

I. — The tsetse-flies (*Glossinae*) of West Africa.

(*a*) General biological characters

(*b*) The different species; their characteristics.

The author distinguishes small species of less than 10.5 mm in length and large ones which are longer. Amongst the first, he mentions the *palpalis* group (*Gl. palpalis, Gl. pallicera, Gl. tachinoides*) and the *morsitans* group (*Gl. morsitans, Gl. longipalpis*). He identified in F. W. A the following members of the second group: — *Gl. fusca, Gl. nigrofusca, Gl tabaniformis*, and *Gl. medicorum.*

(*c*) The habitat of the flies, biological and geographical conditions;

(*d*) The tsetse-fly zones in F. W A.

(*e*) The seasonal migrations of the flies The periodical variations in their geographical distribution due to meteorological conditions

(*f*) Effect of geographical and geological conditions. Correlation between flies and soil.

(*g*) Connection between *Glossinae* and the vegetative and climatic zones of F. W. A. Geographical breeds.

II. — The flies and their relation to diseases caused by trypanosomes in West Africa.

a) Variations in the resistance of different species of animals to the tsetse-fly.

(*b*) Effect of cattle in protecting man from *Glossinae*

(*c*) Biogeographical relations between tsetse-flies and trypanosomes

(*d*) Geographical races of the flies and their virus. Relatively slight danger of the spread of sleeping-sickness in French West Africa.

(*e*) The control of tsetse-flies.

CORPS AND CULTIVATION

361 - **Phenological Observation and Studies in Holland.** — Bos H., in *Cultura*, Year 30, No, 364, pp. 363-379 and Year 33, No. 388, pp 12-22. Utrecht, January, 1921.

The phenoscopic data collected each year in a network of specially-chosen Stations distributed throughout Holland are published by the author. The list of these Stations is as follows: — Balfo, Sexbierum, Groningen, Leeu-Warden, Bergum, Winschoten, Zeegse, Texel, Dalen, Hoorn, Alkmaer, Harderwijk, Naarden, Enschede, Amersfoort, Warsnsveld, Utrecht, The Hague, Rosendaal, Velp, Arnhem, Wageningen, Zetten, Rotterdam, Kapel Avezaath, Malden, Middelbrug, Waterlandkerkje, Schinnen, Nuth, Maëstricht, Gronsveld.

The trees and plants examined are: —

Corylus Avellana, Aesculus Hippocastanum, Ribes rubrum, Betula alba, Prunus avium, Prunus spinosa, Prunus Cerasus, Prunus Padus, Pyrus communis, Fagus sylvatica, Syringa vulgaris, Narcissus poeticus, Crataegus Oxyacantha, Spartium scoparium, Quercus pedunculata, Cytisus Laburnum, Sorbus aucuparia, Cydonia vulgaris, Sambucus nigra, Secale cereale hibernum, Rubus Idaeus, Symphoricarpus racemosa, Salvia *officinalis, Cornus sanguinea, Ligustrum vulgare, Tilia grandifolia, Tilia parvifolia,* and *Lilium candidum.*

The following vegetative phases were noted and registered: —

1) Coming into leaf. On the same tree of average earliness the upper surfaces of the leaves begin to show themselves in certain places.

2) Unfolding of the first flowers.

3) Ripening of the first fruits.

4) Date when most of the leaf-buds are unfolded and the tree becomes green.

5) Date when the leaves begin to assume their autumn tints.

The phenoscopic data collected each year are suitably commentated upon and sometimes form the subject of special publications

As regards the annual commentaries for 1920, the season seems to have been characterised by early flowering owing to the high temperatures in March This early blossoming was especially noticeable in the cases of *Prunus Cerasus, P. Padus, P. spinosa, Cytisus Laburnum, Sorbus aucuparia,* and *Prunus avium.* It is clearly shown that the increase, or rather the height, of the temperature does not affect different plants in the same manner or to an equal extent.

Acer Pseudoplatanus, though its buds swell and open early, at least as far as can be judged from some individuals was rather late in 1920, whereas the planes, which are much later budded soner.

Fraxinus excelsior, of which the phenoscopic periodicity is but little accentuated, was very late, as if the favourable thermic conditions had no effect upon it, *Wistaria* behaved in a similar manner, only flowering at the same time as *Cytisus Laburnum* (the latter, a much later tree, flowered a fortnight earlier than usual).

In April, another fall in the temperature occurred that, in the case of a number of plants, prolonged the foliation and flowering periods. The apple-trees remained in flower for over a month. From May 9 to 11, the temperature fell again considerably. The author mentions, in this connection, a work by SCHIERBEEK, who attributes the cold spell that prevailed throughout a great part of Central Europe from May 10 to 15 to the influence of the energetic renewal of growth on the part of the majority of plants. He is of opinion that the fall in temperature was due to the transpiration of the large mass of foliage which came, almost suddenly, into contact with the surrounding atmosphere.

As the season progresses, the earliness of the phenologic phenomena gradually diminishes until, towards the middle of the summer, the date of the vegetation phases tends to become normal. On the other hand, there is an advance in the appearance of the autumnal tints on the leaves.

As was said above, the data collected sometimes serve as the subjects of special studies and monographs. An article by the same author on the rye harvest in Holland has been included in one of these publications He made use of the documents of 2-8 Stations, and the data refer to periods of information ranging from a minimum of 3 years, to a maximum of 24.

Average Data for Each Place.

Localities	Date	Years of observation
1) Maestricht	15 $^{13}/_{20}$ July	16
2) Rosendaal	16 »	8
3) Suippeling	16 $^{2}/_{25}$ »	19

27) Alkmaar	7 August	6
28) Texel	7 »	10

The geographical position of the Station (its latitude and longitude) undoubtedly have an influence upon the date of the ripening of the rye, and hence upon the time of the harvest.

Complete maturity is reached first in the southern districts, the South-East sector being the earliest ; the harvests ripen progresively later as one passes northwards, the latest crops being in the North-West sector (Alkmaar, Texel).

There are, however, many other factors besides geographical position, which have a decided influence upon the date at which the crops are ripe. The numerous errors in the comparative estimation of the data are due to : —

(1) The race, kind, or variety of rye in question ; thus, a *late* variety may ripen at the same time or later in the south, as an early one in the north. The data given in the present article all refer to local varieties or to the variety known as " Petkuser ".

(2) *Agro-geological conditions.* — In soils rich in water and nitrogen, cereals reach maturity more slowly than in poor sandy land. It

is therefore advisable to carry out the observation work under special conditions, which would give the highest comparative value to the phenoscopic averages obtained. This could be done by the institution of a " Phenological Society ", provided its statutes and regulations were scrupulously observed by the members.

As regards the date of maturity in the case of rye, the author has for many years classed the different seasons under the respective heads of average, late, and early.

An average result may, however, be due to two very different causes: —

(1) The crops may have ripened at an average date in all the localities.

(2) On the other hand, the average may be due to early ripening in some Stations, and late ripening in others. In the second case, the author proposes to substitute the term " mixed season " for " average season ". It has been observed that the differences between the dates of the harvest in the extreme localities are less in early than in late years.

362 - Weather Conditions in South Florida Relative to the Cultivation of Sugar Cane.

— CHANGE. G. M., in *Sugar*, Vol 22, No. 12, pp. 689-690. New York, Dec. 1920.

Apart from the injurious effect of the north and north westerly winds which occasionally prevail, the climate of South Florida is, taken as a whole, favourable to the cultivation of sugar cane.

The period without frost lasts 2 months longer than in Louisiana, resulting in an average increased length of cane maturity.

In studying the effect of frosts in the open field, the author has noted that the cane already resists well; mature canes only may suffer damage and those ready for milling.

In any case, frosts, even though not essentially destructive, should be taken into account.

As a means of control, the author suggests a system of flooding the land to get practical immunity from frosts.

As regards resistant varieties, D 74 is recommended, which has already given good results.

A cross between D 74 and a very hardy Japanese variety should prove of value in Florida. Such a cross has been made, but its practical value has not yet been demonstrated

363 - Theory of Injury Due to Freezing of Fruit Buds from the Protection Standpoint.

— WEST, F. L. and EDLEFSEN, N. E. (Utah Experiment Station), in *Journal of Agricultural Research*, Vol. XX. No. 8, pp. 665-662, pl. 1. Washington, D. C. Jan. 15, 1921.

INTRODUCTION. — The late spring frosts and the early autumn frosts cause damage to the extent of several millions of dollars annually in the United States. The commonest method of protection is to heat by burning oil in pots distributed through the section that is endangered. This method is resorted to on a large scale in the citrus fruit sections of California, and less frequently elsewhere for the protection of such fruits as apples, peaches and cherries.

The success of this practice depends on the economical use of fuel and labour, and it can only be employed in cases of urgent need.

If the predicted minimum temperature is lower than the " critical temperature " or if the predicted minimum temperature is above the " critical temperature ", in both cases it is useless to light the heaters.

It is, therefore, indispensable to know first the degree of resistance of the fruits trees at various stages in their development. Thanks to the previous investigations made by other authorities, it has been possible to draw up a classified list of the " danger points " for various kind of fruit: —

1) At the time when the petals are closed but showing colour · — apple 25° F to 27° F; peach, 20° F to 29 F; cherry 22° F to 29° F, pear 25° F to 29° F, plums and apricots 22° F to 30° F.

At time of blossoming: apple and pear 28° F to 29° F, peach 27° F to 30° F, cherry 28° F to 30° F, apricot and plum 28° F to 31° F.

Fruit setting: apple and cherry, 28° to 30; peach 27° to 30°; pear 28° to 29°; plum 28° to 31°, apricot 28° to 32°.

This paper gives the methods used and the results obtained by freezing on 24,000 fruit buds, most of them being apples and peaches, and also observations on the spring temperatures and yields of fruit in orchards near Logan Utah (1913 to 1920).

METHODS EMPLOYED — 1) Detaching branches with fruit buds in the laboratory by means of a specially designed thermostat, the air surrounding the buds being cooled by means of common salt and ice. The extent of the injury was determined by cutting the buds open and counting those that had been damaged and then calculating the percentage frozen.

2) Branches of trees were bent down into a vessel sorrounded by a second air chamber, the latter being surrounded by a mixture of ice and salt. The minimum temperature was noted, the branch tagged, and the further development of the buds was observed and the yield of fruit determined.

3) Modified method No. 2. Instead of using ice and salt, the buds were cooled by means of evaporating liquid carbon dioxide which in a very cold gaseous condition cooled the buds to the desired temperature.

4) Freezing the whole tree by surrounding and covering it with a 2-walled metal vessel containing ice and salt.

The factors that determine the amount of damage done are:

1) Kind of buds.
2) Stage of development.
3) Minimum temperature.
4) Humidity.
5) Duration of frost.
6) Rate of thaw.

RESULTS — General conclusions may be drawn after examination of the numerous experimental data collected in this way.

1) Ben Davis apples in full bloom have experienced temperatures

of 25°, 26° and 27° F without injury, and 25° kills about ½ and 22°F about $^9/_{10}$. On several occasions, however, apples matured on branches at a temperature of 20° F.

2) With Elberta peaches in full bloom, 29° F or above are safe temperatures. A temperature of 28° F will kill from ¼ to ½; 26° F kils ½ and 22° F about $^9/_{10}$.

3) With sweet cherries in full bloom, 30° F is the safe temperature, but 29° F usually kills about ¼ and 25° F about ½.

4) Sour cherries are hardier than the sweet varieties in full bloom 26° F killed only $^1/_5$ and 22° F only $^2/_5$ of them When the buds were showing colour 23° F did not harm them.

Sour cherries are the hardiest, and then follow in order apples, peaches, apricots and sweet cherries.

5) With apricots 29° F is the safe temperature; 26° and 27° F killed about $^1/_5$ and 22° F killed ½ They are, therefore, fairly hardy, but they bloom so early that they are more exposed to the late spring frosts than other fruits.

6) All the foregoing figures refer to the buds when in full bloom. Starting from this stage, the earlier the stage of development the hardier are the buds but when the fruit is setting the injury is from 5 to 10 % more than when they are in full bloom.

364 - The Effect of Frost upon Roots, and the Best Means of Minimising Injury thus Caused. — JENSEN M., in *The Ugeskrift for Landmaend*, Year 65, No. 51, pp 701-703 Copenhagen, December, 1920

The results of investigations and observations made at Hindrerupgaard (Odense, Denmark) regarding the effect of frost upon plants cultivated for their roots, and the best means of lessening the injury they may sustain. According to the greater or less degree of frost, the state of the soil and of the plants, the roots, after a considerable fall in temperature may be in one of the following conditions: —

1) Capable of being lifted as soon as they are thawed, as they can still be stored.

2) So much damaged that they require at least some weeks free from frost, in order to recover.

3) Injured to the extent of being unable to recover, even if the weather be favourable throughout the rest of the winter.

The author gives the following advice based on his own experience: —

1) If the frost has not been too severe, the roots should be lifted as soon as possible after the thaw and put into hemispherical heaps, from ½ to ⅓ of a metre high, in the case of small roots, while in that of large ones, the dimensions of the pile onght to be about double.

The upper layer consists of roots placed one against another, in direct contact; they should be arranged so that the tip of the root is always directed towards the centre of the heap; the leaves being turned outwards, form a protective layer

In this position, roots that have been lifted resist subsequent frosts much better.

2) When, however, the temperature begins to rise, and the cold is not sufficient to harm the plants to any great extent, the author recommends their being left in the ground, for they keep better under this condition. A certain number can be lifted each day, as they are required for feeding the stock.

365 - **The Use of Smoke-Producing Candles to Prevent the Injury Caused by White Frosts.** — ZANNONI I., in *Giornale di Agricoltura della Domenica*, Year XXXI, p. 75. Piacenza, March, 1921.

The material left over from the war has been used in the most different manners and agriculture has not been the last to profit by it. In the English munitions dépôts there are certain contrivances which were intended to hide the troops at the moment of assault by generating dense clouds of smoke that formed a efficient screen allowing the soldiers to carry out their manoeuvres freely.

These were known as *smoke-generating candles* ; during the time they burnt, which was 6 to 8 minutes, they produced a dense smoke, that extended along the ground ; and rose to a greater or less height according to the atmospheric conditions. These so called candles consist of a cylindrical tin box 8 cm. in diameter, and 14 cm. in height; they weigh 1-4 kg., and are ignited by friction.

When the candle is lighted, it burns under considerable pressure, which carries up the smoke to the height of 1 to 2 metres producing a grey gas, that is perfectly innocuous, as the author tested by standing in the midst of the smoke for some minutes. He inhaled it without experiencing the smallest inconvenience. There is thus no fear of the presence of poisonous gases that might injure the plants, as might ave been expected.

It thus seemed possible that these smoke generating candles could well be used instead of the smoke-producing fires lighted by agriculturists in spring, when they fear the effect of white frost upon the crops, especially the most suceptible ones cultivated in kitchen-gardens, orchards, and vineyards.

The experiments lately carried out by the author at the English camp, at Rivalta di Scrivia, show that there is every reason to believe that the innocuous gas generated these smoke producing candles would afford efficient protection to crops when their young buds are threatened with injury by the early morning frosts.

The smoke of the candles forms dense clouds, which can protect the plants for half-an-hour at least, the exact time depending upon the wind and the hygrometric condition of the air. Therefore, if they were lighted from time to time during the hours when frosts were to be apprehended, they would hinder the formation of hoar frost, and prevent any fear of injury. The efficacy of smoke in protecting crops from frost has been tested already in many localities, where it has long been the practice to light fires of straw. The smoke-generating candles should be placed on that side of the field from which the wind is blowing ; they should be put in a single line, and from 20 to 30 metres apart. Fresh ones ought to be lighted every half hour or oftener, according to the atmospheric conditions.

The author proposes to continue his experiments.

366 - **Soil Reaction as Applied to Agriculture** (1). — I. Demolon, A. (Directeur de la Station agronomique de L'Aisne), La réaction des sols, in *Revue scientifique*. Yr. 53, No. 6, pp. 173-177, bibliogr. of 26 works. Paris, May 1920, and in *Journal d'Agriculture pratique*, Year 84. No. 41, p. 294. Paris, Oct. 1920. — II. Mirasol, J. J. (University of Illinois), Aluminium as a Factor in Soil Acidity in *Soil Science*, vol. X, No. 3, pp. 153-193, bibliogr. of 84 works, tables 9, Baltimore M. D. Sept. 1920. — III. Hasenbaumer, J. (Landw. Vers. Stat. Munster in W.). Einfluss der Bodenreaktion auf die Düngung und Fruchtbarkeit der Kulturböden, in *Mitteilungen der Deutschen Landwirtschafts Gesellschaft*, Yr. 36. No. 5, pp. 80-81. Berlin, Jan. 29 1921. — IV. Gerhing A., Ueber die Reaktion des Ackerbodens, in *Zentralblatt für die Kunstdünger-Industrie* Yr. 26, No. 4, pp. 37-39, Frankfort, Feb. 1921. — V. Wherry E. T., Soil Acidity and a Feld Method for its Measurements, in *Ecology*, Vol. I, No. 3, pp. 160-173, chart 1, Brooklyn, N. Y., July 1920. — VI. Marchadier and Goujon (Directeur et Chemiste du Laboratoire municipal du Mans), Le problème des engrais, in *La vie agricole et rurale*, Yr. 10, No. 6, pp. 81-84. Paris, Feb. 1921.

I. Soil acidity. — M. Demolon gives a brief outline of the origin and nature of soil acidity, and of chemical and physical methods employed for its determination, from the practical standpoint as regards the microflorae and macroflorae in the ground, as well as the question fertilisers and the importance of improving of calcareous land. Considering the fact that soil acidity will constitute henceforth an important factor in the evaluation of fertility and the most appropriate manure to be applied, the author has considered it appropriate to set before the readers the methods of soil analyses at hand. For practical determination, he recommends the Hutchinson method (addition to the soil of a $^1/_{50}$ normal solution of calcium carbonate in carbonic acid, stirred for 3 hours and titrating the non-absorbed residue by employing methyl orange indicator). This is advised in preference to other chemical methods, including the Veitch method, widely practised in laboratories in America (2).

The question of soil acidity, has been studied for many years, especially in England and the United States; the authors desires that this should also be given due attention elsewhere.

II. Aluminium as a factor in soil acidity (3). — The author starts by a bibliographical summary on all question concerning soil acidity and the presence of aluminium in plants and soil.

---

(1) See *R.* 1918 Nos 390, 623, 624, 727 and 1204; R. 1919, Nos. 10, 159, 284, 434, 436, 562, 819 and 1084; R. 1920 Nos. 167, 622, 917 and notes (*N. d. R.*)

(2) Robinson considers that the Veitch lime water method gives good results each time it is employed without any modification of modalities such as length of time, temperature, method of heating and evaporation, mass contact etc (*Soil Science*, vol IX, No, 2, p. 151. Baltimore, Feb. 1920). Of the 5 methods examined by Stephenson, those which were apparently the most in agreement are the Veitch and Tacke methods, preference is given to the second. (Cf. March 1919 No. 284). (*Ed*)

(3) See *R.* 1918, Nos 390 and 727, and *R.* 1919, No. 426. (*Ed.*)

Up till now very little information has been obtained concerning the stimulating or fertilising action of aluminium, and the experiments have given results, both incomplete and unsatisfactory, according to MIRASOL although some aluminium compounds have shown themselves extremely toxic to plants (1).

In the experiments conducted by MIRASOL 3 different types of sour silt loams were employed, all coming from southern Illinois and giving an acid reaction with blue turnsol paper. Their composition is shown in the following table.

		Diameter of particles	Colour of soil		
			Grey	Yellowish grey	Yellow
		mm.	%	%	%
Moisture		—	1.76	1.36	1.61
Gravel		2–1	0.93	1.37	0.00
Sand	large	1.0 –0.5	2.15	1.79	0.21
	medium	0.5 –0.25	5.77	2.57	0.44
	fine	0.25–0.1	10.93	4.09	0.97
	very fine	0.1 –0.05	25.26	20.72	52.35
Lime		0.05–0.005	44.61	50.99	19.54
Clay		< 0.005	10.15	18.45	26.47

The author also gives the chemical analyses of the 3 soils. Evidently all were poor in calcium, rich in aluminium and potash, with an acidity (expressed in lb. of calcium required to 1 acre of soil) equal to 2125, 2813, 2921 respectively for soils Nos. 1, 2, 3.

The experiments were carried out with sweet clover (owing to the antipathy of this plant towards acid soil) to ascertain the following points: 1) the influence of aluminium salts and aluminium hydroxide alone or in combination with calcium carbonate or with superphosphate; 2) the effect of limestone and superphosphate alone and combined; 3) the effect of the removal of some aluminium from the soil; 4) the influence of iron and manganese on soil acidity.

The results of several experiments (the author illustrates the same with excellent photographic plates) indicated that in the absence of calcium compound, aluminium salts were highly toxic to sweet clover when applied in amount chemically equivalent to the acidity of the soil, and fatal when applied in amount chemically equivalent to five times the acidity of the soil. In the presence of calcium silicate, aluminium nitrate was more toxic than aluminium sulphate. Aluminium mono-hydroxide had no effect whatever on the growth of sweet clover when other plant nutrients were supplied in a water soluble form. Calcium carbonate in sufficient amounts corrected the toxicity of aluminium salts by precipitating the aluminium as calcium aluminate. Good results were obtained by applying limestone at a rate equal to the lime requirement, and fair crops were also obtained with 1 ton of superphosphate per acre and good crops with 5 tons per acre.

---

(1) See the recent interesting work of STOKLASA and his collaborators relative to the effect of aluminium and magnesium ions on germination and development of plants. *R.* Oct. 1919, No. 1111. (*Ed.*)

These trials combined with acidity determinations following the HOPKIN's method demonstrate that, contrary to the idea prevalent, superphosphate distinctly causes decrease in soil acidity. The best results were obtained by combined applications of limestone and superphosphate.

When the soil was leached with a solution of potassium nitrate, until the leachings were neutral, the results were no less interesting. From the 3 soils in question was extracted 97 to 99 % acidity, 45 to 50 % aluminium, 14 to 24 % iron, and 3 to 9 % manganese originally contained in the soil; on the other hand extraction with water gave, respectively, 7.2 to 12.4 %; 17.7 to 24.7 %; 2.5 to 8.6 % and 1 to 1.5 %.

Sweet clover was sown on 3 plots leached with potassium nitrate, but it was found impossible to obtain good germination and growth on soils Nos. 2 and 3, in spite of the addition of sandy soil to improve the physical condition, or leaching with water to eliminate excess of salts. MIRASOL considers that this shows an obvious strong saline residue in both types of soil, in spite of repeated leachings. It was only on the grey type (originally less acid), that it was possible to grow the sweet clover. This, although it presented a feeble and chlorotic appearance in the pots filled with unleached acid soil with or without the addition of potassium nitrate as a fertiliser, gave on the contrary, different results in pots containing soil, water leached or leached with nitrate solution, and developed strongly.

After an examination of the behaviour of iron and manganese, the author was able to conclude that: 1) apparently aluminium is the determining factor in the acidity of soils, with especial reference to American types; 2) in some acid soils, iron and manganese may become contributing factors (1).

In so far as aluminium is a factor in soil acidity, it is considered that HOPKIN's method (2) is the best one for soil acidity determinations.

III. INFLUENCE OF SOIL ACIDITY ON MANURING AND FERTILITY. — After having made observations on the important part played by soil acidity, HASENBÄUMER states that injury caused by acidity is most evident on heavy soils or those inclined to heaviness, towards springtime, after persistent drought, and results in a yellowing, arrested development and often even in death of barley and oats, and also of potatoes, radishes, cabbages etc.

---

(1) See also *R.* July 1918, No. 727. (*Ed*)

(2) See *U. S. Depart. Agr Bur Chem. Bull.*, vol 73, p. 114, Yr. 1903. According, however, to the experiments made by STEPHENSON (see preceding note), the HOPKIN's method gives results much lower than all the others

In order to throw light on the varions stages of reaction in the soil; the author proposes the following colorimetric method (1): 30 kg. of dry soil heated with 100 c. c. of calcium chloride solution at 7.5%, stirred thoroughly for 1 hour; 10 c. c. of the soil then filtered and put into sample tubes; 4-5 drops of alcoholic solution of methyl red added and stirred well; and the colour produced noted:

violet	showing	very strong acid	reaction
carmine	»	strong »	»
vermilion	»	medium »	»
orange	»	weak »	»
pure yellow	»	almost neutral or alkaline	

In the last case another 10 cc. of filtrate was taken and 5 drops of azolitmin solution was added, which after filtering gave a distinctly azure blue tint without any sign of violet or red. The soil was therefore clearly alkaline. In the first case, with reference to violet and carmine and also to vermilion, with heavy soils and in the second case blue for sandy soils the various grades of acidity or alkalinity were obviously injurious to plant growth. The author has notified 300 examples of unhealthy plants and this can be explained by the excess of acidity and alkalinity in the soil.

To combat the acidity it has been found advantageons to apply clay marl. The author experimented on acid soil with mixtures of clay marl (85 %) + calcium carbonate, and noticed that the normal reaction occurred with an application of 17.18 gm. per *morgen* (sq. m. 2553). For this reason it is considered advisable to limit the application in accordance with the determination of soil acidity (2).

Alkaline soils should on the other hand be manured according to chemical and physiological acid reactions (potassic salts or sulphate of ammonia). Moreover calciphilous plants should be grown in order to aliminate the excess of alkalinity as far as possible.

The most evident forms of reaction are: — for sandy soils; weak or alkaline; for sandy loam; neutral; for calcareous and argillaceous soil weak alkaline.

IV. GEHRING draws attention to the fact that although it is well known that injuries are caused by acid reaction of peat soils, very little attention is given to the equally certain fact that the continuous use of a single mineral fertiliser gives rise to variations in soil reaction, which may cause damage unless taken in hand in good time. He states that continued action of lime or sodium nitrate may result in counteracting mechanical action in the soil for some time (Meyer and Mansberg) (1). As regards the prolonged use of sulphate of ammonia, this encourages soil acidity. It is not sufficient to determine the quality of fertiliser but it is necessary also to measure the quantity (Lemmermann).

---

(1) KÖNIG and HASENBAUMER testifying to the important bearing of recent scientific soil investigations, draw attention to the fact that the quantitative determination of soil acidity can be made by employing the electrometric method But, in this case, several technical difficulties prevent this method from being put into common practice. This is why they recommend instead the colormetric method with methyl red. (Cf. *Landwirtrchaftliche, Jahrbücher* 1920, vol. 60, No. 2, p. 185) (*Ed.*)

(2) BRIOUX states that in France, the soil in the Caux district is often acid and the custom is to add marl 100 to 400 hl. per hectare every 15 to 20 years, in order to avoid slow and gradual acidification. See *Comptes rendus de l'Académie d'agriculture de France.* Vol. 6, No. 39, p. 934. Paris, Dec. 22, 1920. (*Ed.*)

The author gives practical advice on the alternation of fertiliser applications and supports the Hasenbäumer method described above.

V. Soil acidity and field measure for development. Wherry starts by a discussion in simple terms of the principles of physical chemistry which bear upon soil acidity, and the reasons why the hydrogen-ion concentration (2) should be considered as a highly important feature of solution of any acid substance.

Wherry emphasies the fact that the only really reliable method of determining the said concentration or specific acidity is: 1) by catalysis of an ester; 2) by measurement of the potential due to hydrogen-ion, with a potentiometer (3); 3) by observation of colour changes of indicators whose relations to hydrogen-ion concentration are known. He considers that the salt-solution acidification methods practised are valueless, owing to the fact that the results so obtained are composite, representing both acid originally present + a usually greater quantity produced by the treatment, and would differ widely according to the salt used.

The six indicators which have proved most satisfactory in work with soils are: bromphenol blue, bromcresol purple, bromthymol blue, phenol red, methyl red and phenolpthalein.

The specific acidity or alkalinity of the soil extract is determined by adding first a drop of bromthymol blue to the aqueous extract; if the liquid is coloured green, the reaction is neutral, if yellow it is acid, if blue, alkaline. If acid the process should be repeated with successive indicators.

Indicators	Coloration		
	Acid	Neutral	Alkaline
Bromcresol purple . . .	Yellow —> brown —> magenta	Purple	Purple
Methyl red	Carmine pink —> red —> orange	Yellow	Yellow
Bromphenol blue. . . .	Olive green —> brown —> purple	Bluish purple	Bluish purple

---

(1) See *R.* Oct.-Dec. 1919, No. 1086 (*Ed.*)

(2) On the question of the measurement of acidity by hydrogen-ions, See *R.*, Aug. 1918, No. 839, *R.*, April, 1919, No. 436 and *R.* Feb. 1920, No. 167. (*Ed.*)

(3) According to König and Hasenbäumer (see preceding note) the acidity obtained by means of titration is nearly parallel to the hydrogen-ion concentration (*Ed.*)

If an alkaline reaction employ:

Indicators	Acid	Neutral	Alkaline
Phenol red	Pale yellow	Orange	Dark orange —> red —> carmine pink
Phenolphthalein . . .	White	White	Pale mauve —> carmine

This process should be continued until either an intermediate colour or opposing extremes of two overlapping ones are obtained. The specific acidity or alkalinity can then be found at the head of the corresponding column on the coloured chart included in this article.

The author states that in spite of certain limitations this method is capable of giving definite information as to soil reaction in many cases, and the results obtained by the author on a number of species of native plants (1) have been of considerable significance.

VI. PROBLEM OF FERTILISERS. — MARCHANDIER and GOUJON summarise the present situation relative to the effect of soil reaction on plant diseases (1) and point out that although up to now artificial fertilisers have proved of great economic value, the harmful effects due to their use in excess quantities now begin to be realised, plants are becoming less resistant to insect pests and accumulate less gluten, *e. g* durum wheats cultivated on French intensive culture lines, which are much less glutinous than those cultivated on American extensive lines. The authors recommed the application of complete fertilising stimulants especially waste products etc, to counteract this organic weakening effect due to the continuous use of heavy applications of saline fertilisers.

367 - **Plant Distribution around Salt Marshes in Relation to Soil Acidity.** — WHERRY, E T, in *Ecology*, Vol I, No 1, pp 42-48. Brooklyn, N. Y., Jan 1920.

I. — As a result of very many determinations of soil acidity and alkalinity made with plants growing under the widest possible range of physical and climatic conditions, the author states that abundant evidence demonstrates that soil acidity is closely associated with the distribution of native plants An account of a few observations is here given to illustrate the possibilities of this method in throwing light on the significance of peculiar types of plant distribution.

The following species (2) which are found on territory extending from the northern Uplands southwards in New Jersey chiefly along the coastal area, flourished on soils that proved to exhibit on the whole circum neutral reactions. The reaction reached a specific acidity of 10, or a similar specific alkalinity, but rarely less farther than this from the neutral point: —

---

(1) See *Fühling's Landwirtschaftliche Zeitung* 1917, p 130 (*Ed*)

(2) The common names in these lists are taken from Britton and Brown's " Illustrated Flora " with a few modifications, technical names are in accordance with the American code, but the synonym is given in cases of recent changes which have not been generally accepted, and the names under the international code are likewise added

List I.

Wood reed-grass (*Cinna arundinacea*)
Slender wild rye (*Elymus striatus*)
Low cyperus (*Cyperus diandrus*)
Woolly sedge (*Carex lanuginosa*)
Starry false solomon's seal (*Vagnera stellata*) (*Smilacina stellata*)
Wide-leaf ladies' tresses (*Ibidium plantagineum*) (*Spiranthes lucida*)
American aspen (*Populus tremuloides*)
Starry campion (*Silene stellata*)
Spreading pearlwort (*Sagina procumbens*)
Blunt-leaf sandwort (*Arenaria [Moehringia] lateriflora*) (*Stellaria borealis*)
Columbine (*Aquilegia canadensis*)
Lyre-leaf rock-cress (*Arabis lyrata*)
American burnet (*Sanguisorba canadensis*)
Swamp wild rose (*Rosa virginiana [lucida]*)
Hog peanut (*Falcata comosa*) (*Amphicarpa monoica*)
Herb Robert (*Geranium [Robertiella] Robertianum*)
Whorled milkwort (*Polygala verticillata*)
Shrubby bittersweet (*Celastrus scandens*)
Northern bugle-weed (*Lycopus uniflorus*)
Pale wild sunflower (*Helianthus giganteus*)

More or less closely associated with these species, are others found also in the coastal area, which grow otherwise only in the pine barren area: —

List II.

Brake (*Pteridium latiusculum = Pteris aquilinum*)
Larger pine-barren club-moss (*Lycopodium adpressum [Chapmanii]*)
Pitch pine (*Pinus rigida*)
Panic grass (*Panicum meridionale*)
Panic grass (*Panicum oricola*) (*variety of preceding*)
Pine-barren cyperus (*Cyperus Torreyi*) (*Cyperus cylindricus*)
Twig-sedge (*Cladium [Mariscus] mariscoides*)
Grass-leaf rush (*Juncus aristulatus*)
Grass-pink orchid (*Limodorum tuberosum*) (*Calopogon pulchellus*)
Early ladies' tresses (*Ibidium vernale*) (*Spiranthes vernalis*)
Southern wild flax (*Linum [Cathartolinum] floridanum*)
Inkberry (*Ilex glabra*)
Sheep laurel (*Kalmia angustifolia*)
Stagger-bush (*Neopieris [Pieris] mariana*) (*Lyonia mariana*)
American cranberry (*Vaccinium [Oxycoccus] macrocarpon*)
White thoroughwort (*Eupatorium album*)
Blazing star (*Lacinaria graminifolia var.*) (*Liatris graminifolia*)
Pine-barren goldenrod (*Solidago fistulosa*)
Bushy aster (*Aster dumosus*)

Tests of the soils supporting the above species in the pine barrens have shown them to be, practically throughout, of the high specific acidity of 300.

To explain the occurrence in this coastal area of plants showing elsewhere widely divergent preferences as to habitat, the author states that plants in List I. evidently required an abundance of available lime and other bases, either free or in the form of salts, but necessarily tolerant of high acidity. Those of List II demand high acidity, but must be torlerant of the presence of salts. Other plants which were not found on the coastal regions, but were indigenous to the neutral soil uplands and the pine barren area, apparently were not capable of withstanding the presence of salts in spite of a suitable degree of acidity.

The plants on the following list were observed on soil which when tested showed a low degree of acidity averaging a specific acidity of 3; the high content of the lime and other bases in the glacial material from which the soil is derived, evidently preventing the development of a higher degree of acidity:—

LIST III. *Plants of Rich Woods, Oak Island, Massachusetts*

Slender wild rye (*Elymus striatus*) *
Bottle-brush grass (*Hystrix patula*) (*Asperella Hystrix*)
Woolly sedge (*Carex lanuginosa*) *
Canada lily (*Lilium canadense*)
Trout lily (*Erythronium americanum*)
Bellwort (*Uvularia perfoliata*)
Showy orchid (*Orchis* [*Galeorchis*] *spectabilis*)
Blunt-leaf sandwort (*Arenaria* [*Moehringia*] *lateriflora*) *
Strong-scented meadow rue (*Thalictrum revolutum*) *
Red baneberry (*Actaea rubra*)
Shrubby bittersweet (*Celastrus scandens*) *
Hone wort (*Deringa canadensis*) (*Cryptotaenia canadensis*)
Sweet cicely (*Osmorrhiza* [*Washingtonia*] *longistylis*)
Fringed loosestrife (*Steironema ciliatum*)
Richweed (*Collinsonia canadensis*)
Figwort (*Scrophularia marilandica*)
Wood betony (*Pedicularis canadensis*)
Lopseed (*Phryma Leptostachya*)
Horse gentian (*Triosteum aurantiacum*)
White rattlesnake root (*Prenanthes* [*Nabalus*] *alba*)

The salt marsh mud proved, as usual, to have a specific alkalinity ranging from 30 (wet portions) to as low as 3 (hummocks). Between the woods and the salt marsh is a strip of damp ground a few metres in width supporting a flora quite unlike that of either woods or salt marsh; instead, the species were found to be those elsewhere characteristic of peat bogs, sandy or peaty margins of ponds, sandy barrens, etc:—

LIST IV.

Bog club-moss (*Lycopodium inundatum*) *
Switch grass (*Panicum virgatum*) * (in damp sand)
Blue-joint grass (*Calamagrostis canadensis*) (also in swamps)
Green spike-rush (sedge) (*Eleocharis olivaceae* *) (also in wet bogs)

---

* Found also in the coastal area of New Jersey.

Three-square sedge (*Scirpus americanus*) *
Twig-sedge (*Cladium* [*Mariscus*] *mariscoides*) *
Canada rush (*Juncus canadensis*) *
Turks-cap lily (*Lilium superbum*)
Grass-pink orchid (*Limodorum tuberosum*) (*Calopogon pulchellus*) *
Pink bearded orchid (*Pogonia ophioglossioides*) *
Cross-leaf milkwort (*Polygala cruciata*)
Inkberry (*Ilex glabra*) *
Sweet pepper-bush (*Clethra alnifolia*) *
Privet andromeda (*Xolisma ligustrina*) (*Lyonia ligustrina*) (also in dry barrens)
Highbush blueberry (*Vaccinium corymbosum*) * (also in dry barrens)
American cranberry (*Vaccinium* [*Oxycoccus*] *macrocarpon*) *
Buckbean (*Menyanthes trifoliata*) (also in wet bogs)
Large gerardia (*Agalinis* (*Gerardia*) *purpurea*) *
Small gerardia (*Agalinis* (*Gerardia*) *paupercula*) (also in dryish sands)
Small bedstraw (*Galium trifidum*) (also in wet bogs).

The intervening strips of damp ground would naturally be inferred to be approximately neutral in reaction, but the vegetation is characteristic of admittedly highly acid soil, and the soil in this strip when tested, showed a specific acidity of 300, similar to that of the average sandy barren and peat bog. The reason for the development of this acidity at the border of the salt marsh may be attributed to the fact that sea water is drawn up by capillarity into the soil around the edge of the woods, its bases are absorped by the clay and humus, and acids are set free. That the occurrence of the plants in list 4 on soils of this high acidity is a matter of preference and not a mere matter of tolerance is clearly indicated by the fact that the majority of these plants are not known to grow in any habitat with a much lower degree of acidity than this.

The author's information should go far towards destroying the fallacy that the important, if not the only soil factors influencing plant distribution, are physical properties of the soil.

368 – **Location and Lie of the Phosphate Beds in Western Morocco** (1).— SAVORNIN, T., in the *Comptes rendus de l'Academie des Sciences*, Vol. CLXXII No. 4, pp. 229. Paris, Jan., 24, 1921.

Morocco has rich sedimentary eocene phosphate beds (white or grey sand) in the regions of Beni-Meskine Plateau or El Borouj-Oued Zem which continues towards Kasba Tadla. On the south their width varies from 1-50 km. and from east to west more than 120 km. The reserves are estimated at over 3-4 thousand million metric tons.

The author has observed other beds in the hydrographic basins of Oum er Rebia, Bou Chane, Tensift, and Oued Kçob.

1) THE AHMAR-REHAMMA BASIN. — The middle valley of Oum er Rebia divides the great plateau of Beni-Meskine from that of Selam-R'ereba-Oulad Delim, where the eocene overlays the primary and archean

---

* Found also in the coastal area of New Jersey.

(1) See *R.* Jan. 1921, No. 19. (*Ed.*)

formations (1). The surfaces of the two plateaux are formed of the same lutetian limestones at Thersitées resting on the marly, siliceous and phosphatic strata which constitute the suessonian layer.

The number, value and extent of the phosphate deposits are known in the plateau north of Oum er Rebia but no prospecting has been carried out in the South. The author thinks that they exist, always of a sandy nature, as is shown by the debris around Arab wells. Silico-phosphatic, blocks are also spread over the soil on the southern slopes of Bou Chane and are frequently intercalated near the upper parts of certain layers at El Borouj-Oued Zem.

This basin extends latitudinally for more than 80 km to the east of Lake Zima, the broadest part measuring 30 km. About half (to the south-east) is probably buried under the hydrostatic level.

The maps made by BRIVES and GENTIL show that the lower eocene lies to the west of Lake Zima bordering on the hinterland plain of Safi. This can only mean the sinking of a flexure at the edge of the cretaceous escarpment because it forms part of a great outcrop in which the cenomanian gypsum rises as far as the douar of Biassa. This indication shows the existence of the suessonian under a portion of the neogene littoral.

2) SUPERFICIAL RESIDUES AT CHILCHAOUA. — This name is given to the eocene outcrops mentioned by BRIVES and LEMOINE along the Modgador-Marrakech road (Auk el Djemel, Raïat, Tilda), excluding those mapped along the Chichaoua oued and which the author has not seen.

The limestones at Thersitées here form narrow table lands like the desert " Gours. " The suessonian is spread around them in an irregular arc whose contours are very broken up. The largest dimension from east to west is 18 km and 10 km from north to south.

Prospecting has shown the existence at Tilda of useful beds but less rich than those at El Borouj. The road cutting at Raïat shows a workable bed interrupted by a fault.

No phosphate beds are known there.

3) THE SYNCLINAL OF THE MESKAIA. — This outcrop, easily studied at Khemis des Meskala, is compressed in the limestone which forms a series of undulations to the north of Mtouga. It is very eliptical, and measures 25 km in length by 5 km in width facing South.

A curious form of suessonian in which the lutetian covering is lacking forms the detached plateau of Zned, whose area does not exceed 300 hectares.

The prospecting of these two beds, separated by a crevasse 1 km. in width (road from Tleta el Hanchen to Khemis Meskala) is still to be made. The author knows, however, of the existence of phosphate beds there.

---

(1) It rests on the upper cretaceous layer in the east towards Gada des Selam Rieraba (near the Rehammas), and on the middle cretaceous in the west, near Zaquia Sidi b Madhi er Rhouati (near the Ahmar) (*Author*)

4) EVIDENCE OF THE IBIL. — A minute trace of calcareous fluid exists on the Southern flank of the Ibil (Djebel Ibil is marked Dar Kaïd Mtougui on the 1 : 20 000 map).

This is the point of a synclinal relieving the precedent towards the east and nearly all buried under the alluvial plain of Oulas Jenmouna. The visible part is some hectares in extent, and traces of silico-phosphatic layers can be recognised in it.

5) THE IMI N'TANOUT BASIN. -- The author has fixed the stratigraphical position of an outcrop south of the synclinal, at Imi n'Tanout. This fold finishes in the west 5 km. from Zaouia Sidi Abd el Moumen. It stretches to the east along the borders of the Atlas Mountains as far as Amismiz.

The eastern end, according to BRIVES and GENTIL, lies at the foot of the Kik platau. Almost the whole basin, nearly 15-20 km. in breadth, is hidden under quaternary and oligocene alluvia.

The situation is unsatisfactory from an industrial point of view because the hydrologic basin, probably artesian, floods the phosphates. The prospecting of Imi n'Tanout and Kahira gave encouraging results, but the above remark takes away all practical value from them .

6) TANAOUT OR HAOUZ BASIN. — The author indicates this basin on the evidence of the geological maps. It is separated from that of Imi n'Tanout by a great eocretacious and paleozoic saddle connecting the platean of Kik to that of Tameslouht.

The tectonic disposition is probably the same as in the preceeding basin, and phosphate may be found there.

There only remains to be found indications connecting with it, towards the north east with the synclinal of Kasba Tadla, by Demnat and oued Abid. In short, the great tablelands of Beni-Meskine and Oulad Delim are by far the most important from an industrial point of view. Compared with the immense wealth lying here, the Chichaoua residues have but a theoretical interest; they show the continuity of the tablelands as far as Djebilet and the return to the little or not transgressive position of the suessonian. The other basins give us information as to the formation of the Atlas mountains, the clearness of their folds and their filling up by the aquitanian continent formations shows the importance of the Pyrenean orogenic movement on the edges of the great and middle Atlas Mountains.

As regards the suessonian transgression noted by the author to the south of Ben Guerir and as far as Lake Zima, it shows eustatic oscillations unaccompanied by folding. This regime characterizes all the paleogeographic evolution of Western Morocco during the secondary periods.

369 – **Field Experiments with Nitrogenous Fertilisers.** — I. LIPMAN, J. G , and BLAIR, A. W., Field Experiments on the Availability of Nitrogenous Fertilisers, 1908-1917, in *Soil Science*, Vol. IX, No. 5, pp. 371-392, tables 10, bibliogr., of 3 works, Baltimore M. D., May 1920. — II. THORNE, C. E., Carriers of Nitrogen in Fertilisers, *Ibid.*, Vol. IX, No. 6, pp. 487-494, tables 8. June 1920.

I. — A report of a 5 year period of work started in order to study the relative availability of different nitrogenous materials and loss of nitrogen under a 5 year rotation of maize, oats, wheat and 2-years timothy. Twenty $^1/_{20}$ acre plots were limed and 20 others were left unlimed. Certain plots in each section received no fertiliser, others one element only, others a combination of phosphorous and potassium, and others nitrogen, phosphorous and potassium. All nitrogen treated plots received annually 640 lb. acid phosphate and 320 lb. muriate of potash per acre. Farmyard manure was applied to certain plots at the rate of 16 tons per acre annually and one plot in each section received this + 320 lb, nitrate of soda. Fertilisers and manures were applied annually at about seeding time, except with the autumn sown crops, when ¼ of the mineral nitrogenous fertiliser is applied at the time of seeding and $^3/_4$ as a top dressing the following spring.

The average yield of dry matter and the percentage of nitrogen recovered was greater with nitrogenous mineral materials than with organic materials. Nitrate of soda gave the largest yield and the highest % of nitrogen recovered on the unlimed section and sulphate of ammonia the highest on the limed section. The 4 mineral materials gave for the 5 year period an average recovery of 29.4 % nitrogen (unlimed) and 33.3 % (limed). Of the 3 commercial organic materials, dried fish gave the highest yields of dry matter and % nitrogen recovered on unlimed and dried blood the highest on limed.

Average yield of dry matter mineral and organic nitrogenous materials compared.

		Unlimed section		Limed section	
		1908-1912	1913-1917	1908-1912	1913-1913
		lb.	lb.	lb.	lb.
Average 4 mineral materials:					
(Calcium nitrate, ammonium, sulphate, calcium cyanamide, sodium nitrate).	Grain . .	6 002.5	3 631.2	6 379 6	4 211.2
	Straw, etc .	14 686.4	11 715.0	15 534.6	13 280.0
Average 3 organic materials:					
(Dried blood, dried fish, concentrated tankage).	Grain . . .	5 602 9	3 406 7	6 074.5	4 061.7
	Straw, etc. .	13 503.4	10 812.0	12.596.8	11 253.3

The average annual yield for all the unlimed plots was 28.3 lb. per acre and for all the limed plots 31.1 lb. per acre. In each section the maize and wheat drew most heavily on the nitrogen, for example, on the limed sections, the maize removed on an average 57.9 lb. per acre, which is almost as much as contained in 400 lb. of nitrate of soda. The average total amount removed by crops in general on the limed and unlimed plots was 170.2 and 149.6 lb. per acre respectively.

Analyses of samples of soil from plots of the 2 sections showed that the limed plots lost during 10 years, nearly 250 lb. more of nitrogen than the unlimed plots. The authors suggest that in this case and with no leguminous crops in the rotation to furnish additional organic matter, oxidation may continue with moderate speed without the stimulating effect of lime. The well limed plots furnish a favorable medium for the organisms that destroy organic matter, and this accounts for the heavier loss of nitrogen.

The supply of nitrogen and carbon was best maintained on those plots which received farmyard manure and the said manure + sodium nitrate. The carbon content of these plots has even been increased over the carbon content of the original soil. On the general average, there was less nitrogen and carbon in the soil of limed than of the unlimed section.

The author considers that these results indicate the difficulty of maintaining the nitrogen supply of soil at a high level under continuous cropping with non leguminous crops, even when commercial fertilisers are supplied in generous amounts.

II. — Report of a 5 year cereal rotation conducted in duplicate at the Ohio Agricultural experiment Station. Nitrogen was applied comparatively in the form of nitrate of soda, linseed oilmeal, dried blood, sulphate of ammonia and in tankage. The same comparison was repeated with a potato, wheat, clover rotation. In every case the plots received equal quantities of phosphate, potash and nitrogen. At the experiment station Germantown a 3 year rotation experiment with tobacco, wheat and clover has been in progress since 1903, with plots treated on similar comparison lines to the above.

Results confirm those obtained in the experiments described in Part I With only 2 exceptions in the 40 comparisons, nitrate of soda produced the largest yield. With the tobacco, wheat, clover rotation, the results were similar except on limed land where the yields from sulphate of ammonia slightly exceeded those from nitrate of soda.

370 - **Contribution to the Study of the Fertilising Action of Sulphur.** — NICOLAS, G., in the *Comptes rendus de l'Académie des Sciences*, Vol. CLXXII, No. 1, pp. 85-86. Paris, Jan. 3, 1921.

Investigation has shown that flowers of sulphur when added to the soil in suitable amounts, acts as a fertiliser and increases the crop yield. Sulphur, an element indispensable to plant life, performs at least a double action. It supplies the plant by bacterial oxidation in the soil with sulphuric acid which is directly assimilable, and this sulphuric acid especially in non-calcareous soils facilitates the absorbtion of certain mineral elements (potash, iron, oxide, alumina and even manganese); in addition it also facilitates the work of nitrifying and ammonifying bacteria and thus places larger quantities of nitrogen at the disposal of the plant.

It has even been thought that sulphur favours the development of the root nodules of leguminous plants. With a view to obtaining exact information on this point the author experimented on this subject in 1918 in Algiers and in 1920 at the Jardin des Plantes at Nancy, with peas

Phaseolus, Lathyrus Ochrus and *Lupinus albus* grown in pots to which sulphur was added in amounts corresponding to 100, 200 and 300 kg. per hectare. No very definite result was obtained possibly on account of the high nitrogen-content of the substratum (garden soil). The experiments, however, showed that sulphur in suitable amounts helps the carbonaceous nutrition of the plants. The appended table shows the distribution of starch in the vegetative organs of the haricot and pea, exception being made of the leaves that were already dried up when gathered.

In amounts suited to each species (200 kg. per hectare for *Phaseolus* and 300 kg. for pea), sulphur favours the formation of starch and consequently photosynthesis. MAZÉ and DEMOLON have shown that sulphur is necessary for the development of chlorophyll, that its absence causes chlorosis and that it increases the formation of chlorophyll. Because of this action on the green pigment, the decomposition of carbon dioxide in the air is activated, the carbon is fixed in larger quantities stored in the form of starch; research on the gaseous exchanges in assimilation would probably confirm this assertion.

	Stem (Base)	Stem	Root (Base)
		Phaseolus.	
Without sulphur	Starch very rare in secondary woody parenchyma and at the periphery of the medulla.	Starch very rare in secondary woody parenchyma but abundant at periphery of medulla.	Starch rare in secondary wood parenchyna and at periphery of medulla.
100 kg of S.	Id	Id	Id.
200 kg. of S	Starch abundant in secondary w. parench and per. of pith.	Starch very abundant in s w. p., abundant in per. of pith	Starch abundant in s. w. p. and in per. of pith
300 gk of S	Starch very rare in s. w p , rare in per of pith.	Starch very rare in s w p , abundant in per. of pith	Starch rare in s. w p and in per. of pith.
		Peas.	
Without sulphur	No starch.	—	No. Starch
100 kg of S.	Starch very rare in secondary liber	—	Id.
200 kg of S.	Id.	—	Id.
300 kg. of S.	Starch abundant in secondary liber and in pith Fairly abundant in s w. p.	—	Starch fairly abundant in the medullary rays of the secondary wood.

371 - **Botanical Exploration of French West Africa.** — CHEVALIER, A., *Exploration botanique de l'Afrique occidentale française.*, Vol. I. *Enumération des plantes récoltées, avec une carte botanique, agricole et forestière.* I Vol. 8 vo., XVI + 798 pages. Published by Paul Lechevalier, 12, Rue de Tournon, Paris, 1920 (*Author's communication*).

This work, which has just appeared, was in the press before the war. The map had already been published in Vol. XXVI, No. 4 of *Géographie.* (October 15, 1912).

It gives the limits of the 12 chief plant formations and clearly defines the 5 great zones (the Sahara desert, the Sahelian zone, the Sudanese zone the Guinea zone, and the great virgin forest). The area of dispersal of the 12 wild species of plants most useful to man is shown, as is also the situation of the large natural pastures, which offer a great future to stock-breeding. In the same way, the zone of the Niger flood is also marked, as the soil of this district, after preparation, is suited to irrigated crops.

The object of this work is to make known the vegetation of the regions eplored by the author, his former collaborators O. CAILLE, F. FLEURY and V. MARTRET, and also by his correspondents. CHEVALIER, being unable to explore Mauritania himself, made use, in his description of that country, of information collected by ARNAUD, Col. MOURET, Capt. RONGER, Lieut. G. SCHMIDT, Adjutant CHARLES, Dr. DUCELLIER, M. CHUDEAU, etc.

In the course of the 7 journeys he made in West Africa, between 1898 and 1912, the author collected in French West Africa alone no fewer than 17 000 herbarium specimens.

In Vol. I., he enumerates all the species collected, mentioning the localities and places where they were found. Sometimes he also adds information regarding the habit of the plant, the colour of the flowers, its properties and uses, and its native name. More detailed information upon these points as well as the descriptions of new or little-known species will, however, be found in the subsequent volumes.

CHEVALIER has indeed set himself the task of giving, for all the wild or cultivated species, the details of their dispersion, favourite habitat, biological characters, (periods of vegetation, flowering, fructification, etc.). He will also add the names by which they are known in the dialects of the different countries traversed by him, as well as remarks upon the properties and uses of the principal species.

The last volume will be devoted to the botanical geography of French West Africa.

372 - **Composition of Tuber, Skins and Sprouts of Three Varieties of Potatoes** (1).— COOK F. C., (Physiological Chemist Miscellaneous Disivion, Bureau of Chemistry, U. S. Dept. of Agriculture) in *Journal of Agricultural Research*, Vol. XX, No. 8, pp. 623-635, tables 3, bibliogr. of 13 works. Washington D. C., Jan., 15, 1921.

The composition of the potato varies with the soil and with the fertiliser used, as well as with other environmental and climatic conditions. Since the sprouts depend for their growth on the tubers, the author considers that the composition of the tubers may influence that of the sprouts to no small extent,. The object of the investigation under consideration was therefore to determine, if possible, whether any changes in the composition of sprouts took place after the use of copper sprays employed to control *Phytophthora infestans* or late blight of potato, just as copper sprays apparently influence the composition of tubers. It was also believed that the use of these sprays might influence the time of sprouting, that is, increase or decrease the rest period compared with that of unsprayed tubers.

---

(1) On Rate of assimilation of food from soil by the potato plant and the relative proportion of each of the principal elements contained in the plants. See *R.*, April, 1918, No. 415 (*Ed*)

Samples of Rural New Yorker (No. 12), Green Mountain (No. 15), and Irish Cobbler (No 9) tubers from Maine, taken from vigorous and healthy plants, and also Green Mountain tubers (Nos 3 and 6) from Connecticut, taken from portions of the plots which stayed green the longest, were used for these tests. All the tubers were kept in the dark at an average temperature of 70°*F* from 4 to 8 months. The sprouts which developed on the Rural New Yorker Tubers were short and thick and on the others, comparatively long and branching.

Water extracts of the sprouts, skins and tubers were prepared and the following determinations made: 1) soluble nitrogen, employing 25 cc; 2) soluble phosphoric acid, 50 cc; 3) ammoniacal nitrogen, 5 cc; 4) separation of nitrogenous compounds 100 cc. Copper was determined in certain of the samples by the colorimetric method, using potassium ferrocyanide and standard solutions of copper sulphate.

The analytical data of these 3 Bordeaux sprayed potatoes showed little variation in composition, the age of the sprout apparently influencing the composition more than the variety. Data for Green Mountain sprouts, skins and tubers indicated that the spray did not change the rate of growth or the composition of the sprouts. The percentage distribution of the nitrogenous substances showed the sprouts to contain more protein and less diamino and other basic nitrogen (less than 10 % of the total nitrogen) than the skins and tubers. The younger tubers showed a higher water soluble nitrogen content than the older tubers. The amount of free. ammonia in the young sprouts was constant. More ammonia was found in the skins than in the tubers or sprouts. All samples tested showed copper, the sprouts containing somewhat more than the tubers or skin.

The percentage distribution of nitrogen, phosphoric acid and ash, in sprouts, skins and tubers depends on the relation weight of sprouts and tubers. The action of the sprouts was selective. The solids of the sprouts contained 4 % nitrogen whilst both the others contained less than 2 %.

The sprouts remained fresh, and continued to grow as long as any water was available in the tubers. The sprouts of the Irish Cobbler tubers constituted 17 % of the total weight of the sprouts and tubers at the time the latter were exhausted, while the Green Mountain sprouts under the same conditions, constituted 5.5 % of the total weight. The author suggests that the higher percentage in the first mentioned case is due to increased concentration or activity of the growth promoting agent.

A comparaison between sprayed and unsprayed tubers has shown that there is almost without exception a higher content of solids and nitrogen in the sprayed than in the unsprayed tubers.

373 - **The Proteins of Oats.** — BROCQ-ROUSSEU (Military Laboratory of Veterinary Research), in the *Recueil de médecine vétérinaire*, Vol. XCVIII, No. 2, pp. 44-53. Paris, January 30, 1921.

The author reviews the various works on the proteins of oats, especially the articles written by OSBORNE and his collaborators, and draws the conclusion that the only well-defined proteins found in oats are *avenaline*, a globulin extracted by salt solutions, and obtained in a crystalline condition, and a *prolamine* soluble in alcohol, and belonging to the same group as the gliadin of wheat. The author describes the methods he used for the preparation of these two proteins.

374 - **The Presence of Quinic acid in the Leaves of Certain Conifers.** — TANRET, G., in the *Comptes Rendus de l'Academie des Sciences*, Vol CLXXII, No. 4, pp. 234-236. Paris, January 24, 1921.

Quinic acid, originally discovered in cinchona by HOFMANN in 1790, has since that date chiefly been found in the family of the Rubiaceae, in various species of cinchona and remijia, and in the coffee-plant, and the bedstraw (*Galium*) of our pastures. The acid also occurs in the leaves of Ericaceae such as the whortleberry (*Vaccinium Vitis Idoea*), bilberry (var. *Myrtillus*) and other génera of Vacciniaceae, and has also been discovered in the leaves of tobacco, beetroot, and black currant.

The author has also found it in the leaves of some Abietineae viz., the cedar (*Cedrus Libani*; 5 gm. per kg. dried at 100°C); and the larch (*Larix europaea*; 3.5 to 5 gm. per kg. of leaves). Negative results have been obtained from the ivy and juniper.

375 - **The Injurious Effect of Dead Leaves Upon Germination.** — LUMIÈRE, A., in the *Comptes rendus de l'Académie des Sciences*, Vol CLXXII, No. 4. pp 232-234. Paris, January 24, 1921.

In seeking to account for seasonal rhythm, and for the re-awakening of the soil, both being phenomena independent of variations in temperature, the author previously (1) brought forward the hypothesis, that the soluble products present in the dead leaves and remains of annual plants, as well as those resulting from their fermentation, might perhaps play some part in these periodic phenomena.

To test this theory, the author first soaked, for 12 hours in 2 litres of water, lots containing 500 gm. each of the débris of dead plants; he then used the leaves of chestnuts, plane-trees, and of various fruit trees that had been collected as soon as they had fallen. He found that these solutions possessed very definite reducing properties, and apparently contained phenolic bodies. They completely prevented any seeds from germinating.

---

(1) See *R.* Jan. 1921, No 11. (*Ed.*)

It was necessary to soak the leaves and other plant remains repeatedly before the water used ceased to exert any influence upon germination.

Under natural conditions, the fallen leaves and plant débris undergo progressive disintegration, and finally turn into humus. The author thought it would be worth while to study the effect of the products formed during the first stages of decomposition.

To this end, he left these plant remains to ferment of their own accord in the open air, under natural conditions, and found that the first changes were brought about by micro-organisms, of which the most important is a bacillus of the *Coli* species. As the fermentation process progresses, the medium becomes acid, assumes a darker colour, and emits a strong aromatic odour; at the end of three months, the extracted liquid is brownish-red, and very difficult to filter. As soon as a certain amount has passed through the filter, it becomes cloudy through absorbing the oxygen of the air, the surface becomes covered with an iridescent film, and if the filtering process is repeated the same results are produced, as a result of the formation of insoluble oxidation products.

This solution possesses reducing properties similar to those belonging to the water in which the leaves were soaked immediately after they had fallen, and it has also the same inhibitory effect upon the germination of seeds.

The authors' explanation of the awakening of the soil seems to be confirmed by these first results.

It is well-known that germination is characterised by very intense oxidation processes; in the absence of oxygen, it cannot take place,. At the time when annual plants die, and the trees shed their leaves, the rain dissolves the soluble, reducing bodies contained in this organic matter, and impregnates the soil with substances that absorb the oxygen, thus depriving the seeds of this element, which is absolutely necessary for their germination.

The same processes may continue for a short time at the beginning of the decomposition of the plant remains.

After the leaves fall, the soil will therefore remain sterile until such a time as the atmospheric oxygen that has penetrated into the soil, either directly, or dissolved in the rain water, shall have completely oxidised the reducing matters it contained.

This fact explains the great importance of ploughing operation, which bring to the surface the layers of soil that are full of sterilising agents, and thus destroy the paralysing effect of the latter.

It further accounts for the awakening of the soil in the first days of spring as soon as the higher temperature can hasten the completion of these reacsions, thus bringing to its termination the cycle that should be completed at this season of the year.

The author intends to continue his experments, not only for the purpose of contributing to the accurate knowledge of plant biology, but also with a view to discovering some means of restoring to the soil, early in the spring, the fertility which it loses temporarily during the winter through the agency of the reducing substances of which he has demonstraed the origin.

376 - **Note on the Inheritance of Rust Resistance in Oats.** — GARBER, R. J., in *Journal of the American Society of Agronomy*, Vol. 13, No. 1 pp. 41-43, figs 1, Washington D. C, Jan. 1921.

Report on selection and hybridisation experiments carried out with a view to obtaining rust resistant varieties of oats.

During the summer of 1918, crosses were made between a selection of White Russian oats (*Avena sativa orientalis*) resistant to stem rust (*Puccinia graminis avenae*) and a selection from two high yielding varieties, Minota and Victory (*Avena sativa*), but both very susceptible to rust.

The summer of 1919 proved to be favourable to the development of stem rust and the American varieties were badly attacked, whilst the white Russian variety suffered very little.

The F_2 plants showed sharp segregation and were placed in 2 classes : resistant and susceptible.

The analyses taken as a whole gave the follwing results in F_2:

Minota × White Russian, 104 resistant, 36 susceptible.

White Russian × Victory, 31 resistant, 9 susceptible.

The ratio is therefore 3 :1, indicating that the resistance depends on a single hereditary factor and apparently behaves as a dominant character in these crosses.

377 - **Inheritance of Resistance to Anthracnose, Mosaic Disease and Root Rot of Beans (*Phaseolus vulgaris*) in the Plant Breeding Department, Cornell University, New York, U.S.** — Mc. ROSTIE, G. P, in *Journal of the American Society of Agronomy*, Vol. 13, No., 1, pp. 15-32, bibliogr., of 13 works. Washington, D C., Jan., 1921.

Results of several years observations on the mode of inheritance of the common bean (*Phaseolus vulgaris*) of the factors concerned in the production of resistance to three common bean diseases of New York: anthracnose (*Colletotrichum Lindemuthianum*), mosaic disease and root rot (*Fusarium Martii phaseoli*).

Although the question of inheritance of resistance to disease has, to a large extent, attracted the attention of scientists, and considerable efforts have been made to fix and stabilise this character by hybridisation, up till now the literature on the subject is decidedly limited.

BIFFEN found that resistance to yellow rust (*Puccinia glumarum* Eriks and Henn) in his cross between Rivet, a slightly susceptible wheat, and Red King, extremely susceptible, behaved as a recessive ; all the F_1 plants and approximately 75 % of the F_2 plants having been susceptible.

NILSSON-EHLE arrived at similar conclusions.

VAVILOV in crosses between Persian wheat *Triticum vulgare* var. *fuliginosum* Al. (immune to mildew *Erysiphe graminis* D. C.) and varieties of common wheats susceptible to this disease, secured F_1 hybrids which were immune to mildew.

STUCKEY in breeding varieties of tomatoes resistant to blossom-end rot, found that resistance was transmitted as a dominant character.

TISDALE, studying the inheritance of flax wilt in crosses between resistant and susceptible flax varieties obtained a great variety of results grading all the way from F_1 generations that were wholly resistant to others that were very susceptible. He attempts to explain his results on the basis of multiple factors, claiming that under normal conditions *two* or *three* factors in the homozygous condition would be enough to show apparent resistance. However, under condition exceptionally favorable for infection, only those plants which had factors concerned in the homozygous condition would show resistance. The gradation in the F_1 results might, therefore, be explained on the bases of change of conditions and the number of factors involved.

BURCKHOLDER in crosses between Well's Red Kidney, a type of bean resistant to both α and β strains of *Colletotrichum Lindemuthianum* (Sacc. and Magn) Bri, and Cav., and the White Marrow, a type resistant only to the α strain, but susceptible to the β strain; out of a total of 473 plants tested gave 362 which proved resistant, and 111 susceptible to disease. These numbers show almost an exact 3 : 1 ratio and indicate a single factor a difference between resistant and susceptible plants with respect to the β strain of the anthracnose fungus *Colletotrichum Lindemuthianum* concerned in the cross.

The author has obtained similar results in connection with the inheritance of resistance of *Phaseolus vulgaris* to the 3 diseases, anthracnose, mosaic disease and root rot.

ANTHRACNOSE. — Two strains α and β of this fungus *C. Lindemuthianum* are reported. By crossing Well's Red Kidney (resistant to both strains) with Michigan Robust (susceptible α strains, but resistant to β) of 1970 F_2 plants which were inoculated 1471, showed resistance and 499 susceptibility, which gives an approximate 3 : 1 ratio with resistance dominant.

Another cross was made between selection B (White Marrow var.) (homozygous and resistant to both α and β as the resistant parent), and vars. German Wax and Wardwells' Wax (susceptible). Also additional crosses were made between Michigan Robust (susceptible to α and resistant to β) and White Marrow (*vice versa*).

In all these crosses, unlike the cases heretofore reported when there was apparently only one single factor difference there is on the contrary, where both α and β strains are concerned, a 2-factor difference and a 9 : 7 ratio in F_2 is obtained. This is demonstrated by the data given by the author in the following table (reduced).

MOSAIC DISEASE. — The real cause has not yet been traced. In the hybridisation experiments made up till now, the variety Robust obtained originally from the Michigan Agricultural Experiment Station was chosen as the resistant parent, and the susceptible parent used was almost exclusively the Flat Marrow.

Pedigree Nº	Parentage of hybrids	Resistant	Susceptible	Total
5485	German Wax × Selection B	32	27	59
5478	Wardwell's Wax × Selection B	62	43	105
5486	*Idem*	14	20	34
5557	*Idem*	26	21	47
5558	*Idem*	82	69	151
5483	Robust × White Marrow	216	158	374
5484	*Idem*	90	54	144
	Totals of plants . .	**522**	**392**	**914**

Inoculation was carried out by rubbing vigorously the primary leaves of the healthy plants with affected leaves from plants already attacked, or by using seed produced by infected plants. A large percentage of this seed produced mosaic offspring. Insects contribute to a considerable extent to the dissemination of this disease.

Inspection was made of the F_1, F_2 and F_3 hybrids.

Genetic Behaviour in F_1. — In spite of the numerous possible errors which accompany artificial inoculation tests, a large number of susceptible plants were observed, which indicates that in this case, resistance is a recessive.

Results in F_2 *and* F_3. — A large deviation lies between the two extremes, and it is, therefore, difficult to classify according to the divers categories. In F_2 taking the total number of plants tested as 5272, the number of susceptible plants was 2982 compared with 2290 resistant, (ratio 9 :7). The results obtained for F_3 were analogous. In view of the ratio reported, it may be assumed that 2 factors are concerned in producing susceptibility or resistance to disease. Plants homozygous for both dominant factors might be expected to show a greater degree of susceptibility than plants heterozygous for both these factors. In the same way, plants homozygous for the recessive allelomorphs would be expected to show an equal resistance to that of the resistant parent and superior resistance to that of plants homozygous for one recessive allelomorph or heterozygous.

This explains the variation and intermediate gradations which so often occur in succeeding generations to F_1, and which render so difficult the distinction between each category.

ROOT ROT. — This disease is caused by *Fusarium Martii phaseoli* Burck. According to experiments already made the resistant parent was the variety, Flat Marrow, which, however, unfortunately matures too late, and the susceptible parent was Michigan Robust Pea. which matures somewhat earlier. The ,method adopted was to make a spore suspension of the casual organism in water and dip the beans before planting. The genetic behaviour of F_1, F_2 and F_3 was notified.

F_1 : — The majority of plants showed no resistance, which indicated that susceptibility is at least partially dominant over resistance.

F_2 and F_3 :— In classifying the plants in this case, a certain arbitrary standard must be set up. In the present case, the author divides the plants into 2 groups: 1) those which vary from medium to marked infection; 2) those which vary from medium to normal condition of healthy roots. The following table shows the inoculation results for F_2..

Pedigree of Hybrids	Condition of roots	
	Medium to severe infection	Medium to no infection
Flat Marrow × Robust	4	3
Flat Marrow × Manchurian Pea	3	3
Idem		4
Flat Marrow × Manchurian Branberry		4
Flat Marrow × Marrow		6
Flat Marrow × B. 39	12	10
Flat Marrow × B. 20	9	6
Pea (Dye) × B. 126	2	1
Marrow Flat Marrow	6	5
Flat Marrow × Marrow	8	5
Flat Marrow × Robust	12	9
Idem	13	12
Idem	19	11
Wells' Red Kidney × Flat Marrow	9	7
Flat Marrow × Robust		5
Robust × Flat Marrow	5	5
Idem	6	3
Idem	16	7
Robust × Pea (Dye)		11
Idem	30	14
Pea (Dye) × B. 126	13	10
Robust × Flat Marrow	14	18
Flat Marrow × Robust	10	10
Pea (Dye) × Marrow	11	7
Flat Marrow × B. 39	13	11
Numbers observed	**247**	**187**
Numbers estimated on ratio 9:7	**244.1**	**189.9**

Taken collectively, the results approximate to a 9:7 ratio which indicates the presence of 2 genetical factors with susceptibility dominant. Results with F_3 confirm this hypothesis.

PRACTICAL RESULTS. — The investigations here reported had for their objects, the purpose of studying the method of inheritance of disease resistance and of obtaining varieties of beans resistant to the 3 diseases concerned. From the families reported as homozygous resistant to anthracnose, a number of white seeded resistant strains have been isolated, some of which give promise of becoming good commercial types. One of the parents involved in this cross was also resistant to mosaic and some of the selected types show resistance to both mosaic and anthracnose.

The majority of the crosses made in connection with the studies of the inheritance of susceptibility to both root rot and mosaic were reciprocal crosses between the rot resistant variety Flat Marrow and the mosaic resistant to *Colletotrichum Lindemuthianum* (Sacc. and Magn.) Bri. and Cav. β strain, which is the strain most commonly found in New York State. A few hundred F_2 plants have been selected and isolated from this cross which do not show signs of either root rot or mosaic and which should probably be resistant also to the β strain of anthracnose. Only high yielding plants which mature early should be selected so that the resistant types obtained possess a commercial value.

Some F_2 plants were also selected from reciprocal crosses between Flat marrow and White Marrow; the first is resistant to root rot and to anthracnose β while the second is resistant to the α strain and is at least tolerant to mosaic. It is hoped, therefore, to obtain from a combination of parent characters, the desired progeny resistant to the 3 diseases in question.

378 - **Inheritance of Certain Characters in the Cowpea (*Vigna Sinensis*).** — HARLAND, S. C., in *Journal of Genetics*, Vol. 10. No. 3, pp. 193-205. London, Oct. 1920.

The experiments here described are concerned with the following characters: anthocyanin in stem and leafstalk, colour of seed coat pattern, pod, and flower of *Vigna sinensis*. The author attaches special attention to the colour of the seed coat pattern, which is regulated by 4 existing factors: B = black, N = buff, M = maroon, and R = red. The colour may be due to the following combinations:

Black	**BNMR**
»	**BNmR**
»	**BnmR**
»	**BnMR**
Brown	**bNMR**
Buff	**bNmR**
Maroon	**bnMR**
Red	**bnmR**
White	due to absence of R.

The New Era is the best known and most highly valued variety of *Vigna sinensis* amongst farmers as a forage crop. The seeds are thickly and uniformly dotted with a dark blue anthocyanin pigment on a buff back ground. The pattern is always associated with purple coloration of the tip of the young bed, calyx and peduncle. The pattern taken as a whole is due a factor E which has no visible effect except in the absence of R.

The factor B (black) and E (New Era) both produce as one of their effects anthocyanin coloration of the tip of the young pod, calyx and peduncle, but B produces a more intense coloration than E.

Thus the cross black (BNR) by buff (bNR) will give in F_2 the ratio 3 black to 1 buff, while the cross New Era (ENR) by buff (eNR) will give in F_2 3 New Era to 1 buff. If the factors Band E are inherited independently, a cross between black (BNR) and New Era (ENR) should produce the double recessive buff (be), once in 16 times in F_2, thus:

9 B E N R	3 B e N R	3b E N R	1 b e N R
?	black	New Era	buff

But the actual results obtained by crossing black by New Era showed in F_2 a segregation into 644 black and 197 New Era out of 841 plants. and no buff. The double recessive be does not occur.

These facts may be explained by the phenomenon of repulsion of factors B and E (b and e respectively) during gamete formation. The hybrid F_1 black × New Era (Bb Ee NN) being heterozygotic relatively to the 2 factors, should form 4 sorts of gametes: BE, Be, bE and be, which gives rise in F_2 to 16 different combinations, as shown in Table I.

TABLE I. — *Combinations of* F_2

	BE	Be	bE	be
BE	BBEE	BBEe	BeEENN	BbBe
Be	BBcE	BBeeNN	BbeENN	Bbee
bE	bBEE	bBEeNN	bbEENN	bbEe
be	bBeE	bB eeNN	bbeENN	bbee

One of these 16 combinations (bb ee NN) gives a buff double recessive. On the other hand, being given the existance of a repulsion betxeen B and F_1 the gametes possessing characters B and E and b and E simultaneously cannot develop further, and only the combinations as shown in Table II are formed.

The occurrence of a buff double recessive is therefore excluded and only the individuals black and New Era, ratio 3:1 are obtained.

The evidence is not strong enough to establish the degree of incompatibility between B and E; the authors estimated the repulsion on a basis probably higher than 1:15.

In certain varieties of *Vigna sinensis* the pod is green in the early stages, but shortly before maturity it develops a deep purplish red colour as it develops anthocyanin pigment throughout the pods, calyx and peduncle. It is assumed that one main factor P is responsible for this purple coloration, which produces an effect analogous to that of B and E, but less intensity of colour than that due to B.

TABLE II. — *Combinations of* F_2.
in cases of repulsion of characters B *and* E.

	o	Be	bE	o
o	o	o	o	o
Be	o	BBee	BbeE	o
bE	o	bBEe	bbEE	o
o	o	o	o	o

The relation between B and P as already noted is analogous to that between B and E as regards repulsion between the 2 factors during gametic development; the gametes BP and bp are therefore much more rare than the heterozygotes, following the ratio 7 : 1.

379 - **Inheritance in *Ricinus Communis* L.** — HARLAND, S. C, (Imperial Department, of Agriculture West Indies), in *Journal of Genetics* Vol. 10, No. 3, pp. 207-218. London, Oct. 1920.

Studies on the mode of inheritance of certain characters in the castor oil plant, *Ricinus communis* L.:

(1) *Bloom.*
(2) *Spines* on the capsule.
(3) *Colour* of the vegetative parts.

1) *Bloom.* — Varieties of *Ricinus* are distinguished by the presence or absence of a waxy bloom (factor B). Presence and absence of bloom (Band b) behave as a pair of simple allelomorphic factors. The presence is partially dominant to its absence.

2) *Spines on the capsule.* — The presence and absence of spines on the capsule form another pair of allelomorphs (SANDS) with spininess partially predominant.

Colour. — Two independently inherited Mendelian factors are involved: M. the factor for mahogany and G the factor for green. The absence of the 2 factors (mg) gives a pale type of rose and tinged.

The factor G converts tinged into green (mG = green) and mahogany into rose (MG = rose).

The 4 types resulting from the cross Mg × mb are:

9 MG	3 Mg	3 mG	1 mg
rose	mahogany	green	tinged.

Relation between the factors **S** (SPINES) *and* **B** (BLOOM). — The relation between these 2 factors has been studied in a cross between **Bs** and **bS** The F_2 results are given below:

Family	**BS**	**Bs**	**bS**	**bs**
1	17	0	4	2
2	29	11	9	7
3	31	14	6	5
4	25	10	6	3
5	40	15	10	3
6	78	18	20	4
7	44	14	16	7
8	52	19	18	3
9	48	14	13	4
10	33	20	11	2
11	13	7	6	2
12	39	15	4	5
13	18	16	12	4
14	25	7	8	2
Effective Totals	492	160	143	55
Theoretical Totals	489	163	163	54

From these results it may be concluded that **B** and **S** are independently inherited.

This is analogous in the case of **S** and **M**, **M** and **G** and perhaps also of **G** and **B**.

The relation of **G** and **B** was investigated in a back cross **Gg Bb** × **gb gb**: the following were the results:

Family	**GB**	**Gb**	**gB**	**gb**
1	10	6	2	12
2	6	2	4	7
3	1	1	1	0
4	3	4	5	3
5	14	8	9	9
6	3	1	4	1
7	3	1	0	3
8	7	5	5	2
9	1	5	2	5
10	15	7	13	11
11	1	2	2	2
12	1	5	3	0
13	1	3	4	3
14	9	12	8	17
15	16	17	12	12
Effective Totals	91	79	74	87
Theoretical Totals	83	83	83	83

It will be seen that **GB** and **gb** are in excess of **GB** and **gB**, and it would be unsafe to assume that **G** and **B** are linked. According to the data, the percentage of crossing over between G and B is 46.2, practically independent inheritance.

Relation between the factors **M** (*Mahogany*) and **B** (*Bloom*). — The factors **M** and **B** show repulsion in the cross **Mb** × **mB**.

380 - Study of the F_1 and F_2 of a Hybrid Resulting from a Natural Cross Between the White-Headed Cabbage and the Green Pinnate Cabbage.

— KRISTOFFERSON, B KARL, in *Sveriges Utsade foreningens Tidskrift*, Year XXXI, Part. 1, pp. 31-52, figs. 8, Malmo, 1921

This study of a natural hybrid between the white-headed cabbage and the green pinnate cabbage is part of a series of crossing experiments carried out with different varieties of cabbage during the last few years. The results, in brief, are as follows: —

(1) The hybrid is intermediate in character between its two parents, having a very loose head with an elongated axis, and partly curled leaves.

(2) The median vein of the leaf, as well as the lamina, of the individuals of the F_1 are of a dark violet-red colour quite distinct from that of the parents; the median vein of the white cabbage being green during the summer, and light-red towards autumn, while that of the green cabbage always remains green.

(3) In the F_2, three types of leaf-veining are found: — (1) dark-violet red veins; (2) light violet-red; (3) green, in the ratio of 9 : 3 : 4. The dark violet-red shade is thus due to the presence of 2 factors A and B. A by itself exercises no effect, whereas B can produce a light violet-red coloration in a white cabbage.

(4) As regards certain characters, the offspring in the 2nd generation show every gradation between the extreme or parental, types (continuous variation).

" Head production " is one of these characters. The following table gives the data relating to some of the hybrids, the individuals being divided into 6 classes. In the 1st class are placed all the individuals resembling the green pinnate cabbage, and showing no sign of head formaton. In the 6th class are placed the individuals with compact, well developed head like that of the white-headed cabbage. In classes 2 to 5 are found the hybrids that are intermediate.

No. (year 1919)	Head development						Percentage of individuals with well-devoloped head
	class 1	class 2	class 3	class 4	class 5	class 6	
133	1	19	60	9	6	0	0.00%
134	0	5	11	66	22	11	9.57
135	15	55	202	76	12	2	0.55
136	6	91	379	400	68	14	1.46
137	1	101	836	816	89	14	0.75
138	0	22	430	730	52	13	1.04
139	5	38	754	977	60	14	0.84
Totals . .	**28**	**331**	**2672**	**3074**	**309**	**68**	*Average* **1,08 %**

Similar differences occurred with regard to the following characters: —

(*a*) Hairiness of leaves.

(*b*) Subdivision of lamina.

(*c*) Leaf-form; this shows every gradation between the two extreme forms, viz., the ovoid, nearly round form of the white cabbage, and the narrow, pointed shape characterising the leaf of the green cabbage.

(*d*) Waxy covering of the leaves.

(*e*) Height of plant.

(*f*) Capacity for keeping during the winter.

(*g*) Tendency to run to seed.

(5) With regard to variations in the disposal and distribution of chlorophyll, the following cases were observed: —

(*a*) Two sectorial chimeras, one with a white, the other with a yellow sector.

(*b*) Seedings white and yellow at the time of germination.

(*c*) An area free from chlorophyll on either side of the central vein.

(6) Transgressions (the appearance of characters more strongly marked than those of the parents): —

(*a*) Dark violet-red colour of median vein.

(*b*) Light violet-red of leaf.

(*c*) Leaves still more curly and pinnate than those of the green cabbage.

(*d*) Leaves still more vesicular than those of the green cabbage (resembling those of the savoy).

(*e*) Formation of small bulbs in the axils of the leaves.

(*f*) Plants covered with so much glaucous bloom, that it appears like a grey patina.

(*g*) Height of plant.

(*h*) Tendency to run to seed.

(*i*) Susceptibility to low temperatures.

(7) In the F_2, many forms made their appearance, some of which are similar to the following commercial varities: — Red cabbage, " Wersing" (Savoy cabbage), " Schlitzer" white cabbage, Brussels cabbage, different types of ornamental cabbages.

(8) In the F_2, there were also found plants whose leaves much resembled the turnip-cabbage, or with leaves and inflorescences much like those of broccoli and cauliflowers.

381 - **A Graft Chimara in the Apple in the United States.** — STOUT A. B. (New York Botanical Garden), in *The Journal of Heredity*, Vol. XI, No 5, pp. 233-237. figs. 1. Washington D. C., May-June 1920.

In an orchard in the vicinity of Geneva N. Y. is an apple tree planted there in 1862 which bears two types of fruit; some typical of the variety King (about 20 %) and others nearly identical with the fruits Rockbury Russet.

The occurrence of two more or less distinct kinds of fruit on the same tree may be due to: 1) vegetative variation or bud sporting; 2) top grafting;

3) a chimera : two kinds of cells belonging to stock and scion become associated together in the same branches.

The two first hypotheses are not considered probable, and the proof that the chimeral effect is produced is evidenced by the fact that certain fruits have been found with a segment that is King while the rest are Russet.

It is very probable that the chimera from a scion of King grafted on the root of a seedling of Russet, has grown from a bud that arose on the line of contact between scion and stock. Lateral branches arising from the sector of king are pure for King ; those arising from the part that is Russet are pure for Russet ; those that happen to arise from the lines of contact continue to be sectoral chimeras.

382 - **Maize in Brazil.** — SAMPAIO, S., in *Lavoura e Criação*, Year 6, No. 1, pp. 10-17. Rio de Janeiro, January, 1921.

Three-quarters of the world's maize production is grown in the United States. During the period 1913-1918, the average annual maize production of that country amounted to 69 836 214 tons. Amongst the other countries, the first place is occupied by Brazil, where there are, in round figures, 3 million hectares under maize, some 51 million quintals being produced there annually. Argentina is a very close second to Brazil, and has perhaps outstripped it of recent years. According to the data supplied by the Director of the Brazilian Office of Commercial Statistics, the quantities of maize exported from Brazil and imported by it from 1917 to 1920, were as follows :

Year	Exports		Imports	
	Amount kg.	Value in *paper milreis* (1)	Amount kg.	Value in *paper milreis*
1917	24 054 425	3 926 677	187 142	40 854
1918	14 275 450	3 535 971	1 299 354	166 782
1919	3 475 400	879 072	5 262 426	849 207
1920	(2) 3 207 855	690 436	(3) 2 754 061	437 852

(1) one *paper milreis* = 2s. 2d. at par.

(2) 11 months. According to the data furnished by the *Bulletin of Agricultural and Commercial Statistics*, International Institute of Agriculture, the amount exported for the whole year was 44 260 quintals.

(3) 9 months.

Given, on the one hand, the enormous and constantly increasing consumption of maize in Brazil, and on the other ,the difficulty of competing with Argentine maize which is produced at less cost, owing to the very extensive areas under the crop, and the greater transport facilities possessed by the latter country, it cannot be expected that Brazilian maize will be an important article of export in the near future. It can, however, become of the greatest value, if used to feed the swine which are exported in the form of canned or frozen pork or, still better, as lard.

The average cost of producing 1 hectolitre of maize grain in Brazil is 3.4 milreis; the sale price is 9.7 *milreis*, with a profit of 185 %.

The author mentions the many ways in which maize is used as human food and the countless preparations made from this cereal in the United States by the cook, baker, and pastry cook. He advises that greater use should be made of maize in Brazil, with a view to reducing the consumption of wheat, which is nearly all imported. In 1919, wheat and wheat flour were imported into Brazil to the value of a little over 208 million *milreis*.

383 - **Green Manures and Paddy Cultivation in Ceylon** (1). — MOLEGODE, W., in *The Tropical Agriculturist* Vol LXI, No. 1, pp. 3-6, Peradeniya, Ceylon, Jan. 1921.

The use of green leaves and twigs as manure for paddy fields is now extensively practised and is being recognised as the most economical, safest and best manure to use.

It has now been ascertained that to get a fair increase, at least 2000 lb. should be applied per acre. The first lot should be spread over the fields after the first "*Bin neguma*", or the ploughing, and at this time such leaves and twigs as would take a longer time to decompose should be applied. At the "*Dehiya*" or second ploughing, the leaves and twigs should be ploughed in, and afterwards the second lot should be spread over the ploughed, field. Sufficiently long interval will have to lapse between this and the final ploughing for the leaves and twigs to decompose and mix into the mud.

It is suggested that with green manures and phosphates should be applied at the rate of 1 to 1 ½ cwt per acre, at the final ploughing period.

The following list of trees and plants from which leaves and twigs are commonly in use is given:

Karande (*Pongamia glabra*). Kekuna (*Canarium zeylanicum*). Dadap (*Erythrina lithosperma*). Keppitiya (*Croton lacciferus*). Wild sunflower, Nattasuriya or Titta Sinh (*Tritonia diversifolia*). Adathoda, (*Adathoda vasica*). Wild indigo, Pila Sinh (*Tephrosia purpurea*). Sunn hemp (*Crotolaria juncea*). Bodi (*Psoralea corylifolia*). Hanapatta (*Furcraea gigantea*). Suriya (*Thespesia populnea*) Etdemata (*Gmelina arborea*). Totilla, (*Oroxylum indicum*). Kaduru (*Cerbera Odollam*) and Tarana (*Webera corymbosa*).

Very satisfactory results have been obtained in unproving paddy soils, resulting in large yields. For example — a field of approximately 2 acres was treated with leaves of kekuna (*Canarium zeylanicum*) and karande (*Pongamia glabra*). The yield thus obtained was 104 bus. compared with previous yields of 80 bus. The quantity of green manure employed was about 1500 lb. per acre. Other cases are also quoted showing equally advantageous results.

---

(1) In the same publication of this *Journal* is an additional article on the subject of Green manuring, reproduced from the *Indian Scientific Agriculturist*, Vol. I, No. 12, dealing with the green manure crops grown in various parts of the country with success on wet lands, and ploughed into the soil at the time of puddling. Amongst these are quoted pulse crops such as: — horse gram (*Dolichas biflorus* Linn), green gram (*Phaseolus Mungo*), field gram (*Cicer arietinum*) etc.: — and Sunn hemp (*Crotolaria juncea*), " Boga medeloa " (*Tephrosia candida*), indigo and Daincha. Wild Indigo is recommended for heavy soils, being very drought resistant and with a deep root system. It also thrives well on well-drained land containing coarse sand particles. Hints are given concerning the application of lime in conjunction with green manuring in general.

384 – **Experiments with Varieties of Food Crops in Mauritius.** — *Bulletin No.* 19 *General Series Department of Agriculture, Mauritius*, pp 2-8, Port Louis, 1920.

The crops experimented with have included Sweet potatoes (*Ipomaea Batatas*), Manioc (*Manihot utilissima*), Pistacio (*Arachis hypogea*), Yams (*Dioscorea sativa*), Rice (*Oryza sativa*), and also Soy Beans (*Glycine hispida*), Cow Peas, (*Vigna Catjang*) and Guinea Corn (*Sorghum vulgare*). These varieties included various types known and cultivated locally, together with forms introduced from other countries. The results of the experiments with the last 3 crops are not as yet sufficiently complete to warrant publication. The other details given however afford reliable information concerning imported varieties of food crops, some of which are of superior yielding power to the local varieties.

385 – **Millets for Fodder on Sugar Estates.** — BARBER C. A., in *The International Sugar Journal*, Vol. XXII, Nos 261, 263 and 264, pp 493-494, pp. 613-616, pp 684-686. pl. 3. London, Sept; Nov; Dec. 1920.

A review of the principal millet crops with a view to drawing attention to the importance of improving fodder supplies on sugar estates, and of placing the facts before planters in sugar growing countries where these crops have hitherto been little known. The crops described are as follows: —

	Water %	Proteid %	Ol or Fat %	Carbo hydrate %	Crude Fibre%	Ash %	Nutritive Ratio
				Grain:			
Sorghum (*Andropogon Sorghum*) .	10.7	9.71	3 69	72.38	1.54	2.05	1 : 8.3
Ragi (*Eleusine coracana*)	11 29	9.44	4.93	60.13	6 56	7.65	1 : 7.5
Varagu (*Paspalum serobiculatum*).	8.84	8.04	4.57	65.20	7.39	5.95	1 : 9.5
Kambu (*Pennisetum typhoideum*) .	8.77	9.52	5.33	73.52	0.78	2.08	1 : 9.0
Paddy	12.55	6.35	2.14	65.29	7.84	5.83	1 : 11.0
Wheat	13 33	9.74	1.76	70.18	2.10	2.98	1 : 7.7
				Straw:			
Sorghum (*Andropogon Sorghum*) .	8 70	2.10	1.50	39 67	39.77	8.24	—
Ragi *Eleusine coracana*)	14.16	1.94	0.62	49 11	28.93	5 24	—
Varagu(*Paspalum serobiculatum*) .	8.71	1.97	2.51	47 92	28.84	10.05	1 : 26.8
Kambu (*Pennisetum typhoidum*). .	7.07	1.94	1.33	43 99	37.63	8.04	1 : 23.5
Paddy	11.04	2 70	1.02	40.84	29.23	15.17	—
Wheat	8.71	3 01	0.98	37 93	35.69	13.93	1 : 13 0

Andropogon sorghum (Sorghum) (1) ; *Pennisetum typhoideum* (Bulrush millet) (2); *Setaria italica* (Italian millet) ; (2) *Eleusine corocana* (Ragi) etc.

The foregoing analyses of the grain and straw of millets, paddy and wheat is given (*).

* Reproduced from "Notebook of Agricultural Facts and Figures" by R. C. WOOD.

386 - **"Fructa de lobo" (*Solanum grandiflorum* var. *pulverulentum*) and "Capoeira branca" (*S. bullatum* and *S. cernum*) Forage Solanaceae of Brazil.** — DR SILVEIRA. (Director de Agricultura de Estado de Minas Geraes), in *Characas e Quintaes*, Vol. XXIII, No. 1, pp. 17-19, figs. 2. São Paulo, January 15, 1921.

The author mentions these three wild, arborescent, Brazilian Solanaceae as forming a good stock feed. The foliage of "Fructa de lobo" (*Solanum grandiflorum* Ruiz and Pavon, var. *pulverulentum*) is readily eaten by cattle, in spite of the fact that the leaves, like the trunk, are covered with hooked spines. The fruit is much liked both by cattle and pigs. This plant will grow even on the most sterile ground. A farmer of Caeté who planted it for a pig feed obtained excellent results.

The name "capocina branca" is popularly given to two very nearly-related species, *S. cernum* Vell., and *S. bullatum* Vell. The latter and very probably also the former, is much appreciated by cattle, horses, mules and rabbits. The following percentages were obtained by analyses made at the Chemical Laboratory of the Minas Geraes:

Chemical composition of Solanum bullatum and Solanum grandiflorum.

	S. bullatum Per cent.	*S. grandiflorum* Per cent.
Water	10.47	11.31
Ash	9.98	4.83
Protein	23.92	19.47
Fats	3.16	3.16
Crude fibre	26.78	35.85
Nitrogen-free extracts	25.69	25.38

These plants therefore have leaves richer in protein than those of forage Leguminosae.

As the fruits of *S. bullatum* are greedily eaten by birds of every kind, even before they are ripe, it is difficult to obtain any seeds of this plant.

387 - **Bahia Grass (*Paspalum notatum*) in Florida.** — *Science and Industry* Vol. 2, No. 11, pp. 644-645. Melbourne, November, 1920.

Bahia Grass (*Paspalum notatum*) was first planted at the Florida Agricultural experiment Station in May 1913. The original plot is still growing and from the first gave promise of much value.

---

(1) See *R* Sept. 1917, No. 811. (*Ed.*)
(2) See *R* April 1919, No 459. (*Ed.*)

A further experiment was begun in March 1915, and in September the same year, cattle were pastured on the plot in question both winter and summer from then onwards During the past 4 years the grass has been subject to heavy pasturing. Notwithstanding this fact, it has continued to grow and has made a complete sod over a space now 10 to 12 ft wide. In addition to this, a large number of individual plants have sprung up near by, indicating that the seed has been scattered by the cattle, birds, or wind.

The method here employed gives information on two important points, namely, the ability of the grass to spread and make a good sod while being pastured, and its palatability to cattle. It seems best adapted to a rather moist soil, but has been grown on rather dry sand soil with fairly satisfactory results. It is not likely, however, to be of any value when planted on dry sandy ridges or on land subject to overflow of water. A temperature of 34 to 26° F will nearly always kill all green growth of this grass; although the roots are apparently not injured by light frost.

388 – **Cotton Cultivation in Egypt** (1). — DUDGEON G C., I — The Maintenance of the Quality of Egyptian Cotton, in *Bulletin of the Imperial Institute*, Vol. XVI, No. 2. pp. 160-170. London, April-June, 1918. — II. The Pink Boll Worm and the Cotton Crop of Egypt. *Ibid.*, Vol. X I, No. 3, pp. 362-370. July-Sept. 1918. — III. The Extension of Cotton Cultivation in Egypt. *Ibid.*, Vol, XVII, No. 2, pp. 195-204. April-June, 1910. IV. Cotton Research Board of Egypt. *Ibid.*, Vol. XVIII, No. 1, pp. 117-119 Jan-March, 1920. — V. Agricultural Legislation in Egypt, relating to the Protection of Cotton Crops, *Ibid.*, Vol. XVIII, No. 2, April-June, 1920. — VI. The Egyptian Cotton Problem. LEAKE H. M., in *Agricultural Journal of India*, Vol. XV, Pts. 5-6, pp 485-501, 595-615, and Vol. XVI, Pt. 1. pp. 7-18. Calcutta, 1920 and 1921.

I. II. III. — The total area of cultivated land in Lower Egypt during the 10 years ending in 1914, remained fairly constant, but the proportionate area under cotton increased by nearly 6 % reaching 45.4 % of the total cultivated area of that region. It appears that cotton comes into the crop rotation, in a large part of the country, twice in three years, and that the old triennial rotation has to a large extent disappeared. In Upper Egypt, the fluctuation of the area under cotton is always to some extent affected by the behaviour of the Nile flood, as a certain proportion of each year's crop is grown in the basin lands, which have not yet been placed under perennial irrigation by canals But, even taking this into account, there was a steady increase in the cotton area from 1908-1909 and from 1913-1914, amounting to 5.2 %, for the 6 years.

Excluding the lake area, there are in round figures, 5 600 000 Egyptian acres already cultivated, watered either by summer canal supply or by flood, and there still remain 1 250 000 acres capable of becoming productive of general crops in the future, when properly irrigated (2). Conditions are more favourable in Lower than in Upper Egypt but taking the normal cotton area of Egypt as a whole at 1 716 000 Egyptian acres, it would be possible to cultivate annually upon the same system of rotation as at present in vogue, an additional 1 005 000 acres. To ascertain the actual maximum area, the lake areas must be taken into account, and this when properly drained would probably be suitable in the first place for a rotation of cotton and rice, with intermediate clover. On this rotation, 50 % would be under cotton annually, and would give an additional 312 000 acres to the previous total, making a total of 3 033 000 acres annually capable of yielding cotton.

---

(1) See *R.* July 1913, No. 801 and *R.* August 1915, pp. 1017-1023. (*Ed.*)

(2) See *R.* Dec. 1913, No. 1323. (*Ed.*)

With regard to production, assuming that the new acres be brought under cultivation, it is calculated that a total yield of 11 240 000 quantars (1) per annum should be obtained The climatic and cultural conditions found in Egypt afford the country unique advantages with respect to the production of cotton possessing combined qualities of fineness, strength and length, in comparison with other countries. Experiments have been conducted in India and Arizona in order to establish similar varieties there, but up to the present it has been found that Egyptian kinds grown in these new localities are less prolific and more susceptible to disease and rapid deterioration in quality that is the case in Egypt. Attention is, however, drawn to the fact that the successful results obtained by selection and a consequent isolation of three pure kinds of cotton in America should be regarded as a warning of what may happen if steps are not taken to maintain purity of the existing commercial varieties in Egypt itself (2). The period of life of these last mentioned varieties is not long owing to the fact that the characteristic qualities, which constitute its value, are usually rapidly broken down by cross-fertilisation in the field or by careless mixture of seed in the ginneries. The assumption of the mutational origin of these varieties (3) is supported by what has been found to occur in experimental breeding from Egyptian seed in Arizona (4).

With respect to the kinds of cotton which it is probable may be grown in the near future, it is expected, although that the matter is still under dicussion, and nothing is yet definite, that the Sakellaridis cotton will occupy the attention of growers throughout the Delta for some years, and that there is very little likelihood of a return to the old types, Nubari, Assili and Afifi. Upper Egypt will continue to cultivate Ashmouni, which has been somewhat improved. The most important change in the cultural requirements is that, whereas up to less than 10 years ago, it was not uncommon to continue picking until December, most of the crop is now finished even in Lower Egypt, by the end of September.

This early maturing character has become of the first importance by reason of the ravages of the pink boll worm (*Gelechia gossypiella* Saunders). This pest destroyed practically all the seed of plants which matured late. The average loss, according to Dr. LEWIS GOUGH attributed hitherto to the pink boll pest was about $^1/_5$ the weight of seed + lint in every boll attacked,

---

(1) 1 quantar = 99.049 lb. (*Ed.*)

(2) See *R.* December 1918, No. 1356. (*Ed.*)

(3) See *R.* May 1918, No. 520. (*Ed.*)

(4) See *R.* Feb. 1914, No. 116 (*Ed.*)

e. g. if 35 % of the bolls were attacked, the loss in weight of the crop was about 7 %. Hence the obvious advantage of cultivating early varieties.

The author emphasises the fact that the extreme area capable of being cultivated in cotton can only be attained as the result of a great deal of careful engineering and expenditure.

IV. V. — In view of the great importance of the cotton growing industry to the welfare and prosperity of Egypt, the Cotton Research Board was constituted in May, 1919 to " combine, co-ordinate and extend research of cotton ". On appointing this Board, the Ministry of Agriculture pointed out the economic importance of maintaining the valuable quality of Egyptian cotton, confirming the statements made by DUDGEON (Parts I, II and III).

Field experiments have already been undertaken in a number of different localities on 1) the effect of the subsoil water level on cotton, 2) reducing watering, 3) yielding power of 9 varieties, 4) spacing. The following programme of work has been drawn up:

1) *Botanical.* — The application of plant breeding methods to the purification of existing commercial varieties, and to the production of new and improved varieties. Cotton seed farms are being developed for the multiplication of pure seed strains. Special study will be made of cotton wilt and other fungoid diseases.

2) *Entomological.* — Study of the life history, distribution and control of *Oxycarenus hyalinipennis* (Cotton seedbug) and *Agrotis ypsilon* (cutworm), and a continued study of *Gelechia gossypiella.*

3) *Chemical.* — Observations in connection with manures and subsoil water, bacteriological aspects, investigations arising out of the composition of cotton seed and the changes which occur during storage.

4) *Physical.* — Field experiments and laboratory work on measurement of cotton fibre.

In the *Preliminary Report* (Cairo: Government Press, 1920), a diagram brings out the striking fact that from September 1919 to January 1920, it was more profitable to the grower to cultivate the shorter stapled cottons of the Upper Egypt class such as Ashmouni, than the longer stapled varieties, such as Sakellaridis and there is a danger that this action will extend greatly unless purchasers are prepared to offer a substantially higher price for the long stapled kinds.

Amongst the laws and ministerial orders relating to cotton, it is interesting to note that the irrigation of bersim is prohibited after May 10, or such date as may be fixed annually for certain districts. This law is established to prevent the propagation of cotton worm (1) by the growing of bersim which is another food plant of this pest. Also the roots of cotton, hemp and bamia (*Hibiscus esculentus*) are ordered to be plucked up or cut down, below soil level in such a way that they cannot give rise to any fresh growth, thus facilitating the destruction of bollworms (2).

(2) Usually known by the name of *Heliothis obsoleta* Fab.

VI. — A report of the recommendations made by Mr. H. M. LEAKE, Director of Agriculture in the United Provinces of India, with a view to the maintenance and improvement of the quality of Egyptian cotton, and the increase of yield. These include: 1) the maintenance of the purity of Sakellaridis; 2) the establishment of one or more types with the same intrinsic merits as Sakellaridis, but with an improved vegetative habit; 3) the maintenance of the present classes by a system of purification and the establishment of pure races; 4) the development of types agriculturally better suited to the environment, including the demarcation of type tracts 5) the development of a class of cotton superior in quality to the best Sakellaridis; 6) the division of the country into circles determined, as far as possible, by climatic considerations, and each with its experimental farm; 7) the establishment of a seed farm in each of the circles so defined; 8) the introduction of a system of licensing persons desirous of introduing new varieties. Such a system would enable steps to be readily taken to eliminate the cultivation of any new variety, if considered desirable, and to prevent the adulteration of existing varieties.

For the purpose of carrying the above recommendations into effect, the following further recommendations are made: 1) the division of the Ministry of Agriculture into a series of agricultural, botanical and commercial sections; 2) the establishment of a Ministerial Cotton Committee which should endeavour to co-ordinate practice with the result of these researches; 3) the establishment of an extra ministerial Cotton Board for providing co-ordination between the Ministry of Agriculture and the Physical Service and Irrigation Board, etc.

389 - **Fibre Studies of Philippine Dipterocarps.** — REYES L. G in *Journal of Forestry*, Vol XIX, No 2, pp. 97-104 Washington D C Feb 1921.

The Dipterocarpaceae is pre-eminently the most important timber producing family in the whole Indo-Malayan region an area including the greater part of India, Burma, Siam Cochin-China, the Malay Peninsula, Sumatra, Java, Borneo, the Philippines, and the Indo Malayan Archipelago as far south as New Guinea.

These dipterocarp woods lend themselves to multifarious uses. The soft lightcoloured woods (*Pentacme*, *Parashorea*, and *Shorea*) furnish a large percentage of the cheap construction timber in the Philippines. The red *Shoreas* such as *S. polysperma*, *S. negrosensis* etc. are used for high grade furniture and cabinet work, and the former has been employed successfully in the manufacture of aeroplane propellors. Various species, including *Hopea plagata*, *H. ovalifolia*, *Balanocarpus cagayensis*, *Isoptera borneenis* and *Vatica* spp., produce strong and durable structural timbers, and are extensively employed.

With the continued exploitation of Philippine forests and the increasing cost and scarcity of timber in the north temperate zone, new uses for dipterocarps are coming to the attention of the public The present fibre

study was undertaken with the hope that it might contribute to the present knowledge of the suitability of the said dipterocarps for the manufacture of paper. In the selection of material, the author obtained authentic wood specimens from the Philippine Bureau of Forestry. After isolation of sufficient fibrous material, measurements were made of all fusiform non-septate fibres, which in the Dipterocarpaceae consist almost entirely of libriform fibres and tracheids; the latter are much pitted, shorter, proportionately wider, than the former but only constitute a small percentage of the fibrous material.

An examination of the tabulated measurements leads to a number of interesting deductions.. There is apparently little variation in the fibre length of the Dipterocarpaceae as a whole, but individual variations are both striking and significant Fibres seem to be longest in the softer wooded species such as *Anisoptera* spp. 1.76 mm, *Dipterocarpus* spp. 1.77 mm, *Shorea eximia* 1.76 mm, *S palosapis* 1.54 mm., and *S Teysmanniana*; 1.68 mm., compared with the harder woods such as *Hopea* spp. 1.40 mm, *Balanocarpus* 1.38 mm., *Vatica* spp. 1.43 mm., and hard *Shoreas* 1.46 mm. A similar variation also exists between different species of the same genus, and the author considers that other things being equal, the fibre length of dipterocarp wood varies indirectly to the density An interesting variation is found in woods of like density where pores distinctly vary in size The figures indicate that fibre lengths are directly proportional to the size of the pores. (compare Nos. 40, 39 and 38)

The soft, light coloured woods *Shorea eximia, Pentacme* spp. and *Parashorea Malaanonan* offer possibilities as a source of raw fibre in the manufacture of pulp and paper.

There seems no reason why these fibres should not be used advantageously either alone or mixed with bamboo, Manila hemp, maguéy (*Agave americana*), sisal and other long-fibred stock. At present. the coniferous stock *Populus tremuloides, P. deltoides* and *P. grandidentata* are the most important hardwood species in the United States from the standpoint of paper manufacture. The average fibre length of these species is 1.13 mm. as compared with the light coloured dipterocarps enumerated above, which average 1.60 mm.

390 - **The Coconut Palm in Brazil.** — DE MORAES, P., in *Brasil Indicador*, Year I, No. 1, p. 9, Rio de Janeiro, January 1921.

The coconut palm which is a native of America, grows almost wild along all the northern coast of Brazil, and is cultivated without difficulty throughout nearly the whole country. It begins to bear fruit before the age of 7 years. In the northern States of Brazil, where the coconuts are not gathered and used, a very important source of revenue is neglected, as is shown by the State of Parahyba, where the coconut palm is more or less cutivated, and in 1912, there were 115 900 trees in full bearing. If an average crop of 50 nuts per tree be assumed this amounts to 5 795 000 nuts per annum, which sold at 50 *reis* apiece (the minimum price) gives the sum of 289 750 *milreis* (1 *milreis* = 2s. 2d. at par).

This amount would be considerably increased if the value of the fibre, or coir, were added. According to RIDEAU 1000 coconuts furnish 836 kg. of coir, but even allowing for only 500 kg. of coir per 1000 nuts, this if it fetched no more than 150 *reis* per kg. would bring in 434 625 *milreis* (1 230 858 fr. at par). Thus, the State of Parahyba, by neglecting to gather the coconuts, loses altogether 724 375 *milreis* annually.

There are more than 100 million coconut palms whose nuts are never gathered in North Brazil. The author strongly urges that such a source of natural wealth should be turned to account.

391 - **Experiments in Sowing Seeds of *Cassia auriculata* in India.** — BENNETT H. C., in *The Indian Forester*. Vol. XLVII, No. 1, pp. 25-29, Allahabad, Jan. 1921.

An account of the experiments carried out at Golla, Anantapur, to determine the cheapest successful method of raising *Cassia auriculata* ("Tangedu"), a shrub which yields the most valuable tanning bark in India.

Six different methods of sowing, each on an area of not less than 5 acres, were tried namely:

1) Broadcast sowing on untouched soil.

2) Sowing in furrows about 2 ½ ft. apart and 4" to 6" deep.

3) Broadcast sowing followed by close ploughing in one direction.

4) Broadcast sowing followed by close ploughing first in one direction and then at right angles.

5) Close ploughing in one direction followed by hoeing with a 3-pronged fork (or "goru"), seeds sown in the furrows made by the prongs which are about 6 in apart and finally the whole gone over by a "guntakah" or iron plate drawn by 4 oxen in the same direction as the original ploughing was done to root out grass, turn up the soil, and cover the seeds.

6) Dibbling seeds under trees in soil turned up to a depth of about 6 in. by a spike or crow-bar.

Results. — The cheapest successful method was found to be No. 2. which cost 14 annas, per acre, and by it sufficient seedlings were obtained to stock any area with about 4 800 plants per acre. By method 3 at double the cost, about 27 times as many seedlings were obtained as by method 2, and were somewhat more advanced in growth at the end of a year. By method 5, about twice as many seedlings were got than by employing methods 3 and 4 and they were still more advanced in growth than those obtained by those too methods. The cost was 2-7 rupees per acre more than with method 3 and 8 annas 6 pies more than with method 4. Sowings under bushes and late sowings were failures.

The author suggests a further experiment, employing method 2, but making the furrows 10 ft. instead of 2 ½ ft. apart and thus tending to ensure sufficient regeneration and considerably less expense.

It is possible to grow "Tangedu" on land which can be ploughed, but which is too poor to yield profitable field crops.

392 – **The Cultivation and Preparation of Para Rubber in Burma** (1). — *Bulletin* No 7 *Department of Agriculture, Burma*, pp. 1-31 appendices 2, Burma, December 1920.

A general review of the soil, climate and methods of cultivation best suited to Para rubber.

Attention is drawn to the fact that in Burma the *Hevea* tree matures ready for tapping 5 to 6 years after planting. The stem is then usually 18 in. in girth at a height of 1 ½ ft. from the ground level. As it is the size of the tree rather than its age which determines its fitness for tapping and as, at any time in the age of the plantation, the area of bark up to a height of 3ft. from the ground, represents the capital of the planter, a considerable amount of care is necessary in the selection of the trees to be tapped. The point is emphasised that no tree should be marked up for tapping unless it be at least the girth indicated above. Tapping begins in September and is conducted without interruption, up to mid July. The flow of latex increases steadily from October to December, and then decreases up to February.

The usual method of tapping in Burma is known as the " one-third single cut " *i. e.* the tapping is conducted by means of a clean single cut and is always confined to only a third of the area of available bark. The second year's tapping is conducted over the second ⅓ of the bark surface adjacent to the first ⅓, but as the girth of the tree has naturally increased by that time, tapping begins at 2 ¼ ft. above ground instead of the prescribed 1 ½ ft. the first year. To complete this process 18 months is found necessary, and at the end of that time, the tapping is conducted on the remaining ⅓ of the bark surface, and this time at 3ft. above ground level. It thus takes 4 ½ years to tap once round the bole of the tree.

The following year the tapping is recommended at the 3ft. level and proceeds for 1 year over the depth of 1 ½ft. untapped bark which lies just above that treated at the first tapping, and is continued over the renewed bark that has gradually re-covered the surface first tapped. In succeeding years the afore-mentioned process is continued following the same method as before over the invariably re-covered surfaces.

The yield of rubber varies considerably, but the mean output is about 8lb. per tree per annum a yield which would probably be higher if the trees were planted further apart. The loss of soil fertility through scouring and leaching by heavy rain during the monsoon period is doubtless another contribution to the low yields, but it is recommended that by planting fewer trees to the acre *e. g.* 90 to 100, growing cover crops in the early rains, deferring weeding till the beginning of dry weather, disc harrowing regularly and carefully over a good mulch of green manure crop, and by more economical manipulation of the latex, an estate with trees 10 to 15 years old should yield at the rate of 350 to 400 lb. per acre per annum of dry rubber.

Lists of some suitable catch crops, cover crops and green manure crops are given as follows and details of general cultivation and treatment are also added.

---

393 - **Pruning Experiments on Young Tea.** — *Quarterly Journal of Indian Tea Association Scientific Dept.* Pt II, 1920, and *The Tropical Agriculturist* Vol LV, No. 5, pp. 312-314. Peradeniya, Ceylon, Nov., 1920.

The results the of first and second years' pluckings after cutting down young tea at heights varying from the collar, up to 24 in. from the collar.

In the experiments made with Assam, Burma and China tea the percentage of deaths from collar pruning was 8 %, while from cutting to 2 in. above the collar, only 1 % of the bushes died. With still higher cutting the percentage of deaths was the same or slightly less. Except for the formation of a snag, the bushes cut at 4 in. gave equally as good bushes as those cut lower and averaged ½ maund per acre more than the 2 in. cut bushes cut in the 2 years test. This extra yield is, however, obtained at the cost of this dangerous snag which would certainly lead to trouble in districts where the white ants are prevalent. The 2 in. method is then, more satisfactory all things considered. It is true that the bushes thus formed are low, but it is probable that the yield can be greatly increased by leaving the bushes unpruned for the second year's plucking. The experiments under consideration were conducted under unusually unfavourable conditions, and the serious drought undoubtedly reduced the expected yield from the unpruned tea. Under normal circumstances the indigenous varieties would certainly have given more.

With the bushes which were not cut down, but " cut across " at varying heights, it appeared that the higher the bush was cut, the greater was the yield obtained These high-pruned bushes gave yields higher than would be obtained from the average clearance. The bushes were planted at 3 years old raised from seed, and then had 2 years growth unpruned and unplucked. At the time of cutting across, therefore, they were already a fair size. It should however be noted that with those cut across at 24 in, although giving a high yield, the crop was obtained entirely from the middle of the bush, and the outer part appeared very weak and was attacked by red rust (*Cephaleurus mycoidea*) (1), and brown blight (*Pestalozzia Hartigii*) and brow blight. It is very doubtful whether the present yield can be increased or even maintained from these high-cut bushes, whereas from those cut at 4 in. and below it is expected eventually to have well formed bushes, giving very high yields. By systematic cutting out of the centres of the bushes originally cut at 18 and 24 in. respectively, it seems possible that well formed bushes could also be made, but collar pruning at present is the only method advised for the said bushes.

---

(1) See *R.* Feb. 1919, No. 266 (*Ed.*)

The cutting out of centres is, however recommended for 12 in. cut bushes, and this would secure the advantage of an early high yield, and a satisfactory frame.

394 - **Studies on Manuring Tobacco.** — I. WIMMER G., Ueber den jetzigen Stand unserer Kenntnisse und Erfahrungen in der Tabakdüngung, in *Mitteilungen der Deutschen Landwirtschafts-Gesellschaft*, Year 36, No. 10 pp. 166-168. Berlin, March 6, 1921. — II. VAN DIJK, J., Bemestings proeven bij de tabak op het veld in 1919, in *Medeelingen van het Deli Proefstation temedan Sumatra*, Series 2, No. 14, pp. 3-38, Year 1910.

I. — RESULTS OF THE EXPERIMENTS HITHERTO MADE IN MANURING TOBACCO. THE PRESENT STATE OF OUR KNOWLEDGE ON THE SUBJECT. — The basal manure used for tobacco crops is a dung poor in chlorides, preferably mixed (horse and cow dung).

Nitrate of sodium is little used, partly on account of the fact that tobacco treated with it often burns badly, probably because of the easily fusible deposit of alkali nitrates on the leaves, and because the leaves dry badly.

Sulphate of ammonium (50 to 100 kg. per hectare) or Norwegian calcium nitrate (in double the quantity) are employed ; the latter is very suitable, on account of its high lime content. The author found, as a result of many experiments, that ammonium nitrate makes the cigars burn quicker. Good results have been obtained from cyanamide, and much is hoped from synthetic urea. No conclusive proof has been obtained as to the effect of green manures on the burning properties of tobacco.

Potassic fertilisers are very necessary for tobacco. In Alsace, the fields where this crop is to be cultivated give in the autumn 400 kg. per hectare of potassium silicate (" martelline ") in addition to stable-manure. Sulphate of potassium is not used, as it is supposed to impart an astringent taste to the tobacco, which, however, has not been observed in Germany.

Experiments were made by KITZINGER for the purpose of determining the effect of manuring upon the quality of cigars, but all smokers are not of the same mind as to the results. Further, the results of tests as to efficacy of potassium carbonate are not in agreement.

A heavy application of stable-manure renders the use of a phosphatic fertiliser unnecessary. Where, however, such fertilisers are necessary, it is advisable to choose Peruvian guano and scories (1), and to avoid fertilisers containing a large amount of sulphates.

As the tobacco plant is calciphilous lime should be added to the soil, if the latter is deficient in calcium.

All these rules as to manuring are of secondary importance in comparison with the method of drying the tobacco during and after growth, especially from the point of view of its burning properties, the chief quality required in smoking tobacco.

II. — MANURING EXPERIMENTS CARRIED OUT IN TOBACCO FIELDS. — Experiments were made in Sumatra, in 1919, in order to observe the effect of manure upon leaf production and the vigour of the stem. The fertilisers used were superphosphates, ashes, ammonium sulphate and guano.

---

(1) Similar results were obtained in Italy with scories. See AMPOLA and JOVINO : Il ferro nella combustibilità del tabacco, in *Gazzetta chimica Italiana*, Vol. I, p. 367, Rome, 1902 (*Ed.*)

The best results were obtained, as regards stem growth, by a fertiliser containing nitrogen, phosphoric anhydride and potassium in the proportions 1 : 3.6 : 1.

A fertiliser in the proportions 1 : 3.3 : 1, however, generally improved the combustibility of the fermented tobacco.

An excess of superphosphate hinders the growth of the plant (1)

395 – **Cultivation of Citrus Trees in Tunisia.** — GUILLOCHON, L. (Assistant of the Botanical Service of Tunisia), in *La Vie agricole et rurale*, Year 10, Vol. XVIII, No. 2, pp 28-30, 1 fig. Paris, January 8, 1921.

Unlike Algeria, Tunisia does not possess large areas suitable for planting with Aurantiaceae and such land as is well supplied with water, and where sufficient manure can be obtained, is already occupied by the orange-gardens belonging to the natives. Since 1912, however, several French landowners have bought orange-gardens from the natives (chiefly in the Nabeul district).

New plantations have also been made which are doing well, and it may be said that the cultivation of citrus trees is becoming a thriving industry in the Regency, oranges and mandarins being exported each year; the first consignments are dispatched usually about January 1.

During the war, large quantities of these fruits were supplied to the army.

According to the latest statistics (published in 1918), there are in Tunisia 61 000 orange-trees of which the production is estimated a 13 500 quintals.

According to the laws of July19, 1890, and of November 25, 1915, and to the decree promulgated under date of April 15, 1920, Tunisia is authorised to export to Marseilles free of all customs-duty, from August 2, 1920 to July 31, 1921, 5000 quintals of oranges, 10 000 quintals of mandarins, 5000 quintals of lemons, and 2000 quintals of citrons.

The principal citrus-fruit producing centres of Tunisia are. — In the neighbourhood of Tunis, Bardo, Manouba, Sokra, Ariana. In Cap Bon: Hammamet, Nabeul. In the Centre, near Sousse: Teboulba Mokenine. In the region of the oases: Gabès, Deggache, Tozeur; that is to say, in the coast districts, where great humidity of the atmosphere is combined with a minimum temperature that never falls below 4° — 5° C. and a mean temperature varying from 10°C to 16°C.

In the old, established gardens, oranges trees are the most plentiful, followed, in order of importance, by lemon and mandarin trees.

The new plantations consist of almost equal numbers of orange and mandarin trees, but in some cases the owners have added a few bergamots, citrons, and shaddocks.

Oranges do best on sandy clays or clay loams, and sometimes in default of these, a marly soil is selected, but pure clay is avoided, for the trees grow badly in it on account of its physical composition. Further, clay becomes very cold, as soon as the first autumn and winter rains fall, just when the fruits of the Aurantiaceae ripen. Under such conditions, the oranges should be grafted on *Citrus triptera*.

---

(1) For manuring experiments at Havana, see *R.*, June 1920, No. 637. (*Ed.*)

Frequent irrigation is necessary in summer; the first manuring consists of 30 to 40 metric tons of night-soil or farm-yard, or stable-manure, per hectare.

Windbreaks are indispensable.

Some citrus-growers plant Seville orange stocks on which they subsequently graft; others transplant the stocks, when already grafted, from the nursery with the earth adhering to their roots, which are lifted almost entire. The former is the more economical method.

Intercalary crops of vegetables are planted between the trees. In winter, these consist of peas, French beans, and garden beans, in summer, melons are grown.

When the grafts have taken, they are more susceptible to the damp caused by the irrigation of the intercalary crops, and it appears best to discontinue them at this period; some cultivators, however avoid the difficulty by choosing plants that do not require much water.

In a garden where the lines of trees are 10 m. apart the intercalary crops may occupy a strip of 6 m., thus leaving clear 4 m. of soil around each tree.

Irrigation is practised from May to October; it may be reckoned, that 12 irrigations are indispensable during these months, 500 to 800 cubic metres of water per hectare being used each time. Each tree is irrigated separately, a basin being excavated round it.

The orange and mandarin trees are allowed to grow almost naturally, but they are pruned in such a way that their lowest branches are at 2.50 m. above the ground, which facilitates ploughing between the trees.

The varieties most commonly grown in Tunisia are, in order of commercial importance. — The Maltese orange with delicate flavour sweet, juicy slightly acid, a fine, almost round, fruit and a thin skin ; the Maltese blood-orange which is similar, but blood-red when quite ripe ; the meski orange, which has an insipid taste, a great favourite with the natives ; the Jaffa orange, with large oval fruit, rather thick skin, pulp delicious and melting in the mouth ; the various kinds known as navel oranges or with fruits inclosed and called " double oranges " ; Clementine, a hybrid between a Seville orange with narrow long leaves, the Granito variety, and a mandarin; it is a very good fruit of a fine red colour, and agreeable scent, ripens early (November to end of December), very juicy and sweet

The mandarins include the flat type, with fruits varying in size according to the manner in which the tree is cultivated, and the blood-mandarin, which has hitherto been of little commercial value.

The fruits that are picked up from the ground are sold on the spot at a low price, but those gathered from the tree are packed, the common varieties being put into cases or barrels ; the choice ones, of good colour and free from marks, are wiped, wrapped in tissue paper, and arranged in layers in deal cases, which are usually dispatched as postal packets.

Diseases and Pests. — Sooty mould (*Capnodium salicinum*) is very common, especially in the orange gardens belonging to the natives.

Septoria glaucescens, on the fruits of the mandarin orange-trees, has begun to be a rather troublesome disease in some orange-gardens.

Gummosis is prevented by grafting on Seville orange trees or other resistant stocks, as well as by leaving a heap of soil round the trunk to prevent the irrigation water coming into contact with the root-collar of the tree. In order to control this disease, the hard, cracked, bruised cortex should be removed as soon as the malady appears, the wounds should be disinfected with carbolic acid, and cauterised with a mixture containing tar.

The injurious insects are: The dipteron, *Ceratitis capitata*, and the scale insects *Chrysomphalus dictyospermi minor*, *Parlatoria zizyphi*, *P. pergandi* and, more rarely, *Aspidiotus aurantii*, and *Ceroplastes sinensis*. *Ceratitis capitata* is controlled by daily picking up and burning all the fallen, rotting fruits; whereas the scale-insects are best combated with lime-sulphur washes, or paraffin emulsion. If the trees are seriously attacked by these pests, the treatment should be repeated 2 or 3 times successively at intervals of 8 days

396 - A New Fruit "Masan" (*Zizyphus Jujuba*) Suitable to Certain Parts of Ceylon. — *The Tropical Agriculturist*, Vol. LV, No. 4, p 252. Peradeniya, Ceylon, October 1920

This thorny tree has been successfully grown up to a height of 800 ft. in India where the rainfall is scanty (25-35 in.), and the temperature 50 to 150 F.

Attention has been drawn by Prof. WOODROW to the fact that *Zizyphus Jujuba* has not been cultivated as much as it deserves. It is found growing in abundance in many parts of Ceylon in a wild state, but the fruits are small and of an inferior quality, and practically no attention has been paid to it except for the removal of thorny branches for fencing grass lands and palmyrah gardens. It is recommended now to use lands at present lying waste and unsuited for any other cultivation, and various tracts in the Western and Eastern Provinces.

The plants should be spaced at least 26 × 26 ft., and to raise the trees, seeds should be sown and when 2 years old budded with a superior variety as low down as practicable. No care and cultivation is required except to keep the land free of weeds and to turn up the soil lightly before and after the monsoon.

The best fruits are elliptical 2 in. in length and 1 in. thick. The trees start fruiting the first year, but a regular harvest can be relied upon the third year after budding, when one plant will produce from 82 to 150 lb. per season. The tree may be grown to perfection in scanty rainfall districts and is benefited by pruning in January or February.

397 - **The Timbers of the world** (1). — ELWES, H. G in the *Quarterly Journal of Forestry*, Vol XV, No. 1. pp. 63-67. London, Jan. 1921.

A publication (1) which has been much wanted by timber merchants, architects and users of wood generally for a great many years, is here reviewed by ELWES. Attention is drawn to the difficulty of acquiring the knowledge necessary to write on timbers both from the scientific and practical side owing to the number of tropical trees in the various continents as yet unidentified or described botanically. Especial value should therefore be attached to this book which contains information acquired by the author A. L. HOWARD during 40 years of business, during which he has probably purchased or imported, converted and studied the properties and uses of a greater variety of timbers than any other on an.

ELWES remarks on several points which will doubtess be rectified in after editions, but emphasises the fact that the account of the various timbers imported and known as mahogany is perhaps the most complete and accurate in the whole work, and the same may be said of the oak. Here for the first time in books on timber is found a good account of the beautiful form of this wood known as brown or red oak The causes which produce this change of colour in individual trees or parts of trees remain unexplained, notwith standing Prof. GROOM's investigation of the fungus found in some of the trees showing this change.

Reference to the " Jarrah " (*Eucalyptus marginata*) and other woods used for paving blocks, in which elm is not included, goes to show that the foundation on which the blocks are laid, coupled with the careful selection of wood, are very material points which have not in many cases been sufficiently considered.

A reprint of LASLETT's experiments on mechanical testing of the principal timbers is included, and also a chapter on the " Artificial seasoning of timber " by S. FITZGERALD.

398 - **American Trees for Forest Planting in France.** — BUTTRICK P L, (Assistant Professor of Forestry, Michigan Agricultural College), in *Journal of Forestry*, Vol. XVIII, No. 8, pp. 815-822, Washington D. C December, 1920

Recently there has been much discussion of the possibility of the use of American tree seed and nursery stock for forest planting in the devastated regions of France.

The author draws attention to the importance of understanding fully the nature of the species required rather than offering species suitable only for conditions prevailing in America. French foresters have for many years experimented with exotic species and are familiar with possibilities of planting some of the western conifers etc. The author has in this article made an annotated translation of the notes on American species taken from the list of exotics mentioned in the latest edition of a standard French textbook on forestry (2). According to a recent communication of the Director General of the Service des Eaux et Forêts to the American Forestry Association the seeds of certain species that are little known in France, will be given special care and study and will be planted in the nursery of the forest school at Barres. The national arboretum is located there, and most of the species mentioned have first been tested at this Institution.

LIVESTOCK AND BREEDING

399 - **The Bacteriophagous Microbe** (1) **the Agent of Immunity in Pest and "Barbone".** — D'Hérelle, F. in *Comptes rendus de l'Academie des Sciences.* — Vol. CLXXII No. 1, pp. 99-100. Paris, January 3, 1921.

The author had hitherto only been able to study the bacteria-destroying microbe in intestinal diseases such as bacterial dysentery, enteric fevers, and fowl cholera ; in all these diseases, he isolated a bacteriophagous microbe attacking the pathogenetic agent. It still remained to be seen whether this microbe is only present in intestinal diseases, or whether it is a general means of protection.

In July, 1920, the author studied a severe outbreak of " barbone " that raged in western Cochin-China. From the excreta of buffaloes which had resisted the disease, the author isolated and cultivated a microbe that devoured the bacteria of " barbone '. It is only met with exceptionally in the excreta of buffaloes living in immune regions.

Immunity to artificial infection was produced by injecting into a buffalo a very small amount of serum obtained by the action of this bacteriophagous micro-organism upon a culture of the bacteria of " barbone ". From the excreta of rats that had survived an epidemic of rat-plague (to which were due some cases of bubonic plague localised at Bac Liew), the author succeeded in isolating a micro-organism that attacked Yersin's bacillus, the pathenogenetic agent of plague in human beings), and of which he was able to cultivate several generations. He proposes to ascertain the degree of immunity conferred by these cultures, and to study how they may be used as a prophylactic vaccin against bubonic plague.

The author states that, having occasion once to examine silk worm nurseries where *flacherie* was rife, he found that such insects as escaped the disease owed their immunity to a similar bacteriophagous microorganism.

The conclusion to be drawn from these researches is that the protection afforded by the action of these microbes is of general occurrence. Every time an animal recovers from a bacterial disease, or resists the infection, a race of bacteriophagous microbes that wage war upon the pathenogenetic agent can be isolated from the contents of its intestines. In cases of septicaemia, the subsequent passage into the circulatory system of the bacteria-destroying micro-organism can sometimes be momentarily observed. The normal and permanent habitat of the latter is however, the intestine.

400 - **Anti-Rabies Inoculation of Large Herbivora.** — FINZI G., and RONDELLI A. (R. Scuola Superiore di Medicina veterinaria di Torino, Istituto antirabbico Pasteur dell'Ufficio d'Igiene di Torino), in *La Clinica veterinaria* year XLIII, Nos. 17 to 19, pp. 457-463, Bibliography of 18 works. Turin September-October, 1920.

The authors hope that the Sanitary Authorities will advise the anti-rabies inoculation of all large herbivora that have been bitten by another animal suffering from rabies, or suspected to be affected by that disease. Hitherto the law has required that all such herbivora should be immediately killed. In order to show that anti-rabies inoculation is capable of effecting a cure, the authors mention the case of a draught-horse, which although it was not subjected to this treatment until the 12th day after being bitten by a mad dog. nevertheless recovered completely.

For the inoculation of large herbivora, the authors advise the adoption of RIEMLINGERS' method, with the modifications they have introduced: the sub-cutaneous injection of a complete emulsion, in 150 c.c. of distilled, sterilised water, of the entire brain of a rabbit with fixed virus, that has been 72 hours in ether. At intervals of 4 days, 2 other injections are given similar to the first. In the 10th day, a last injection is made with the same emulsion, which however, must only have been 48 hours in ether.

According to the authors, the fixed virus-ether method of vaccination will also given certain results, provided it is carried out as follows: — 1st injection the same as the above-mentioned; 2nd injection *idem*, but at an interval of 3 days from the first, 3rd injection after 3 days, the virus used having been 60 hours in ether; 4th injection, after 3 days, with virus that has remained 48 hours in ether. The duration of the anti-rabies treatment is from 9 to 10 days.

401 - **Distemper of the Pig.** — MCGOWAN J. P., in *The Scottish Journal of Agriculture*, Vol. III, No. 4, pp. 407-414, Bibliogr. of 6 works. Edinburgh, Oct. 1920.

A discussion of the occurrence of this disease as a pure epidemic among pigs without any complicating factor, introduced by new arrivals into a formerly healthy piggery. The usual symptoms associated with distemper were exhibited, but attention should be drawn to the so-called distemper smell which showed a peculiar resemblance to the so-called doggy smell " also noticeable in the case described '.

A post-mortem examination showed that nearly the whole of the lung of the right side, and the left lung, with the exception of the posterior lobe were in a state of grey hepatisation. The heart etc. showed no evidence of disease.

The author has recommended the precautions which should be taken to avoid the spread of this epidemic including vaccination, isolation, feeding, care of the styes etc. Antiseptics and disinfectants should not be used in the piggery except for washing the boots before entering the pens. Emphasis is laid on the fact that cats and dogs etc. should be rigidly excluded from the piggery, owing to the following interesting and important fact:— While the disease was at its worst previous to the initiation of the above mentioned recommendations, 4 dogs on the farm took distemper, 1 died, 2 were shot owing to the far advanced stage of the disease and 1 only recovered. The fact that this epidemic occurs amongst dogs may possibly contribute towards the devising of a method for combating the said disease, far more effectually than all other remedial measures previously undertaken. Prophylaxis by means of a vaccine prepared from cultures of the distemper organism cannot be regarded by any means as the most important agent used in its subjugation.

After complying with the recommendations mentioned in the infected piggery in question, within 2 months, out of 100 pigs born, 15 were killed off because they showed signs of some disease in an advanced stage, none died of distemper, and at the end of these 2 months, the disease could not be detected in the piggery.

402 - **Stephanurosis of Swine and Its Pathenogenetic Agent.** — SKRJABIN, K. J., in the *Bulletin de la Société de Pathologie exotique*, Vol. XIV, No. 1, pp.47-54, Bibliography of 26 works. Paris, January 12, 1921.

In 1834, NATTERER discovered, in Brazil, in some Chinese pigs, nematodes localised in the adipose peri-renal tissue, and enclosed in cysts containing one or more of these parasites. The nematodes were studied from the zoological standpoint by DIESING, and named *Stephanurus dentatus* Dies (1839). Subsequently, they were found in the most different parts of the world (America, Africa, Australia, and the Far East). In spite of its wide geographical distribution, and the large amount of scientific literature of which this parasite has been the subject, its zoological characters have not yet been determined. The author gives a description of the males of this nematode, which he has able to study in the helminthological collection at the zoological museum of the National Academy of Science at Petrograd. (There were no female specimens in the collection).

403 - **Spontaneous Pyobacillosis in Rabbits.** — COMINOTTI, L. (Istituto di Igiene e Polizia sanitaria della R. scuola Superiore di Medicina Veterinaria in Milano), in *La Clinica Veterinaria*, Year XLIV, No. 3, pp. 45-60, Bibliography of 39 works. Milan, February 15, 1921.

A distinct disease of enzootic character and chronic nature, sometimes breaks out among tame rabbits kept in hutches. It is distinguished by the formation of abcesses in the sub-cutaneous comnective tissue of different parts of the body. The author has discovered that the pathogenetic agent of this malady is a variety of *Bacillus pyogenes, i. e., B. p. cuniculi.*

404 - **The Prophylaxis of Poultry Diseases** (1). — TERNI, C, (Co-Director of the Station for the Control of Stock Disease, Milan, in the *Giornale di Medicina veterinaria*, Vol. LXIX, No. 46, pp. 667-672. Turin, November 13, 1920.

The observations made by the author in 1920, at the time of a widespread epidemic of fowl cholera affecting the poultry in nearly all the provinces of the valley of the Po, prove that breeding-birds usually remain immune, or soon recover from the disease, which however rages among chickens hatched during the year, and of the age of 2 or 3 months. The susceptibility to infection increases after the age of 4 months. In this epidemic, as in all preceding outbreaks of the malady, it was found that the infection increased with the intensity of the poultry-trade, that is to say, when large quantities of young fowls changed hands (from July onwards), and the severity and virulence of the disease diminished with the fall of the later summer and early autumn rains. As compulsory sanitary measures for preventing poultry diseases, the author advises:—

---

(1) For Poultry Diseases see also: *R.*, Dec., 1915, No 1313; *R.*, May, 1916, No. 533; *R.*, July, 1917, No. 646; *R.*, April, 1918, No. 438; *R.*, April, 1920. No. 439; *R.*, Oct., 1920, No. 1005. (*Ed.*)

1) Prohibiting the contamination of running water by throwing into it the viscera of fowls, or by washing in it poultry that have died of disease or been killed because of it.

2) Isolating all poultry (especially webbed-footed birds) in an enclosed space until the disease has died out in infected localities.

3) Prohibiting all trade in poultry in infected districts, the exercise of more careful supervision of markets and shops where poultry is sold retail (especially near the limits of the "octroi"), for as a rule, there is a tendency to despatch infected birds to the markets of the great towns.

As regards prophylaxis, it is necessary not only to vaccinate and revaccinate the old birds, regularly every year, but also to treat the chickens when they are about 2 months old, for vaccination at that age protects them from the disease during the sale time (about 1 year).

The experiments carried out on a large scale by the author during the epidemic have shown the advantage of using, for vaccination again fowl cholera while the disease is developing, a vaccin obtained from cultures in broth (preferably in chicken-broth), which have been kept for 4-5 days at 38° to 40° C., and then killed by the addition of 0.5 % of carbolic acid and 1 % of ether. In these cultures, the number of bacteria is somewhat limited, whereas the exogenous toxins, to which is due the first vaccinal reaction that enables the organism to defend itself immediately against contagion, are present in large quantities. Five to eight days later, fresh inoculations can be made; they will increase the power of resistance acquired some hours after the first inoculation which, as a rule, is sufficient to protect the poultry during the period of the epidemic. After the 3rd inoculation, the birds can usually ingest infected viscera with impunity, even if containing amounts of virus that would with difficulty be exceeded under natural conditions. They can even resist inoculation with virulent blood; this protects them against the possible transmission of the disease by means of blood-sucking insects.

The doses of vaccin-culture to be given are as follows:—

1 c.c. for chickens over 2 months old.
2 c.c. for ducklings, goslings, and young turkeys.
3 c.c. for adult ducks, geese and turkeys.

For the preparation of the serum, the author used, by preference, donkeys and mules, and obtained an excellent product by subjecting the animals to a course of treatment lasting 2 months.

[404]

Equidae are very susceptible to the bacillus of fowl cholera, therefore the first subcutaneous inoculation must not exceed 0.25 to 0.5 c.c. of a 24 hours' culture in broth. After 8 days, a subcutaneous injection of 3 c.c. can be made; this should be followed by one of 5 c.c., and subsequently by an endovenous inoculation of 10-100 c.c., as soon as the reaction caused by the last subcutaneous injection is finished. When a dose of 50 c.c., in the form of an endovenous inoculation, produces no bad effects, a serum is obtained, 2 c.c. of which will cure fowls suffering from a severe attack of the disease; it is however, advisable to repeat the dose during the course of 24 hours.

The serum thus obtained also serves for sero-prophylaxis, and if administered in doses varying from 2 to 5 c.c. according to the weight of the bird, will protect it for over one month dating from the period of contagion.

405 - **Test of the Value of some Concentrated Commercial Foods in the Trentino, Italy.** — GRAMATICA and SERINGHETTI (San Michele Experiment Station), in the *Bolletino del Consiglio provinciale di Agricoltura*, Vol. XXXIV, No. 3, pp.36-38. Trent, February 15, 1921.

At the Agricultural Experiment Station of San Michele (Province of Trento), the authors, in order to be able to reply to the repeated questions of agriculturists, carried out experiments with certain concentrated foods, which were on sale in large quantities at the end of 1919, viz., " moko " (flour of *Vicia Ervilia*), " fruges lin ", " palmes " and " panello di seme di pomodoro ". (tomato seed cake). As a control, " son pour vaches " (" cow bran ") was used. Each food was tested on a lot of 4 cows, 4 other cows being used as a control group. The results obtained were as follows; —

The bran did not increase the live weight or the milk yield. " Palmes " was tried twice on different animals; the average increase in live-weight was 13.3 kg., and 11 kg. per head in 15 days, but the average milk yield decreased, respectively, by 2.42 kg. and 7.2 kg. per head.

The " fruges lin " gave an average increase in weight of 12 kg. per head, and produced no difference in the milk yield.

The tomato cake, as compared with " palmes ", gave a slight increase in live weight (4 kg. per head in 15 days), but the milk yield decreased in that time by 4.4 kg. per head per day.

The conclusion arrived at was that these 3 foods were better suited for draught cattle and those to be fattened for the butcher, than for milch cows.

" Moko " has proved very well adapted for feeding hogs. This flour, which has only been on the market a few years, should be fed dry, or soaked in cold water. On account of its rather bitter taste and characteristic smell, the animals do not eat it readily, and some breeders have reported that there have been cases of death amongst their pigs after the use of this flour. In the experiments made by the authors, it was given cooked (400 gm. being added to the ordinary fodder at first); this amount was gradually increased up to 700 gm. per head per day.

The average live-weight increase was 400 gm. per head per day, and even reached 640 gm. No injurious effects were observed. The authors are of opinion that " moko " is an excellent feed for pigs, and probably also for cattle, provided it is cooked. In this form, it is better liked by the animals, and all possibly injurious substances have been rendered innocuous.

406 - **Experiment with "War Forages"** (1) **in Germany, Hungary, Switzerland and France.** — I. Honcamps, F. and Blanck E., Untersuchungen über den Futterwert der Nebenprodukte und Abfälle der Obst- und Traubenweinbereitung (Mitteilung der landw. Versuchsstation Rostock i. M.), in *Die landw. Versuchs-Stationen*, Vol. XCII, Nos. 5 and 6 pp. 275-290, numerous plates, Berlin, 1919. — II. Weiser, S. and Zaitschek, A., Über Strohaufschliessung aus der Königl. ungar. tierphysiologischen Versuchstation in Budapest), in *Die Landw. Versuchs-Stationen*, Vol. XCVII, Nos. 1-2, pp. 57-92, 6 tables, Berlin, 1920. — IV. Rapport de l'Administration centrale des établissements fedéraux d'essais et d'analyses agricoles sur les essais effectués durant la periode 1913-1919, presented by Dr. A. Schmid, Central Administrator, Berne-Liebefeld, in *Annuaire agricole de la Suisse*, Year 21, pp. 1-17, bibliography of 23 works. Lucerne, 1920. — V. Gouin R , Les substitutions alimentaires dans la ration du cheval, in *La vie agricole et rurale*, vol. XVIII, year 10, No. 1, pp. 1-4, Paris, January 1, 1921.

I. — The dearth of forage that prevailed during the war caused it to be replaced to an increasing extent by the by-products of wine-making. Poot gives the composition of the fresh pomace of apples, pears, and grapes, and Sooboda that of the same pomaces after ensilage.

Formerly, the nutritive value of grape pomace was much over-rated, until Weiser showed that it is much less than that of hay of average quality. If, however, the grape-stalks are removed, the value of the residuum is much increased.

The authors carried out their experiments with dark and light apple pomaces, with ordinary grape pomace powder, and with Neuss grape powder which is said to have been disintegrated, in order to render it more digestible. The authors give some analyses. The animals used in their experiments were 2 adult Rambouillet sheep, and the basal ration consisted of hay mixed with poppy-cake.

The authors confirm the preceding results obtained by Kellner and conclude that dry apple pomace, and probably also pear pomace. can be used as a feed in all cases, but that there are great differences in the composition of this substance, which depend upon the raw material and the method of preparing it (2). On the other hand, dried pomace powders should be considered as roughage with a nutritive value which may be compared, if not exactly to the straw of cereals, at any rate to rice waste.

---

(1) For concentrated cattle foods used during the war, see *R.*, Feb., 1920, No. 223. (*Ed.*)

(2) For apple powder, see also *R.*, april, 1920, No. 442. (*Ed.*)

II. — Feeding experiments with sheep, lasting for 8 days, the basal ration being hay to which were added the following war foods: — (1) Mixture with extract of rumen; (2) a gelatinised feed comsisting of spelt husks, gelatin, buckwheat flour and condiments; (3) chopped maize stalks; (4) the seeds, or rather the integuments, of the seeds of sugar-beets; (5) ground bean pods; (6) nettlemeal, probably a residium from the extraction of texile fibre; (7) sugar-beet stalks. The authors give analyses and tables.

The first food, as Morgen said, can be regarded as of nearly the same food value as coarse wheat bran (1).

The second contains nitrogenous substances in a very digestible form, whereas the digestibility of the other matters is low (even below 40 %), and if the raw protein falls below 8 %, this food has but little value. Certainly where there is a dearth of feeds rich in protein, the gelatin is worth taking into consideration.

The third food is comparable to chaff, and can be used with success for ruminants, and even for horses, but is not at all suitable for fattening pigs.

The fourth food gave bad results, owing chiefly to the large amount of indigestible fibre present.

The fifth food has the same nutritive value as pea-pod meal.

The sixth food is of less value than straw, and is thus only a bulky feed.

The seventh food is equivalent to the leaves and crowns of beets.

III. — The scarcity of forage also in Hungary during the war caused attention to be given to the disintegration of straw. Out of the many processes employed for the purpose, the Ministry of Agriculture chose the Lehmann pressure system. In 1918 the authors repeated the preceding experiments made by Altmannsberger in 1903. They took 2 adult sheep and gave them a basal ration of hay with disintegrated straw, the amount fed being from 220 to 550 gm. of dry matter per head per day. Sometimes 25 gm. of blood meal was added. The forage remained the same throughout the experiments, and its composition was always known

The disintegration of straw for 4 hours under a pressure of 4 atmospheres, in a boiling lye of caustic soda, increases the digestibility of the fibre and of the nitrogen free extracts by 12,13 and 25 %, respectively. The concentration of the alkaline lye has little effect upon the digestibility of the mixture and acts differently upon the various substances; thus a higher degree of concentration increases the digestibility of the fibre whilst it decreases that of the nitrogen-free extracts.

The experiments show that the Lehmann pressure method is capable of considerably increasing the nutritive value of the straw of winter cereals; and that the best way of disintegrating the chopped straw consist in boiling it for 4 hours in an autoclave under a pressure of 4 atmospheres;

---

(1) For experiments made in Italy with the contents of the rumen as cattle food, see *R.*, May 1919, No. 621. (*Ed.*)

1.5 kg. of 96 % caustic soda and 200 litres of water being added per quintal of straw. In this manner, a tasty food with an appetising smell, and decidedly acid reaction (1) is obtained that can be directly fed, and of which the nutritive value, always allowing for the absence of digestible albumen, is equivalent to the nutritive value of best hay. Although the disintegration entailed a loss of 11-14 % of the dry matter, yet even when allowance is made for this loss, the starch content of the crude straw is found to have been increased from 56-77 % by the process.

The authors think that the best and most practical method is to prepare a large quantity of the straw by LEHMANN's pressure method, using an autoclave of 14 cu. m., sufficient to provide food for 250 head of cattle daily.

They also made comparative experiments by varying the method of disintegration.

In the 2nd experiment, the straw was disintegrated under ordinary pressure, by boiling it for 6 hours in an alkaline lye composed of 8.3 kg. of caustic soda, and 240 litres of water per quintal of straw. This method under ordinary pressure, necessitated a strong concentration of caustic soda, and as soon as the operation is finished the straw has to be washed in water until the alkali is removed and then quickly dried at 30° or 40° C. These successive washings, not only remove a large amount of the dry matters, but the non-nitrogenous extracts are much less available than when the operation is carried out under pressure. The digestibility of the crude fibre is but little increased. This 2nd method entails a great deal of work, expense, and precautions that are unneccessary in the case of the 1st method. Further, it has been proved that disintegrated straw economises albumen to a greater extent than entire straw or hay.

A 3rd experiment for the purpose of ascertaining the effect of caustic soda upon the disintegration process, was carried out by treating the straw with steam alone, or with steam and lye together. The treatment with pure steam decreased the dry matter of the straw 3 %, and it was found, by feeding experiments with horses and sheep, that although steam treatment increases the digestibility of crude straw, it does not do so to the same extent as the combined treatment. Moreover, the straw, when merely steamed, was stiffer and less appetising, as well as less economical of nitrogen, than when boiled in soda lye. Steamed straw is, however, preferred both by horses and sheep, hence good qualities of straw may well be treated in this manner, although it is chiefly useful for woody straws of inferior quality. This remark also holds good, and even to a greater extent, in the case of alkaline disintegration. Steamed straw, and still more alkalised straw, have a more beneficial dietetic action than the crude product.

Kitchen salt added to the straw before steaming decreases the digestibility of the crude fibre.

---

(1) Due to the liberation of acetic acid. (*Ed.*)

[406]

The authors obtained a very soft, but appetising straw with an agreable smell, by treating it with slaked lime. But, in this case, as when soda is used, under ordinary pressure, the straw needs thorough washing before it can be fed. Further the lime method seems to have no advantages over Lehmann and Beckman's systems (1).

IV. — Since 1913, the Central Administration of the Federal Agricultural experiment and Analysis Stations of Switzerland has tried to extend agricultural experimentation further by dividing the work among the Stations of Oerlikon, Berne-Liebefeld, and Lausanne. Moreover, the scarcity of the food supply during the war, and the resulting introduction of the most varied substitutes, necessitated the different products being subjected to preliminary scientific experiments.

The Report of the above-mentioned Central Administration announces that the account of the manurial and cultural experiments still in progress will shortly be published. It will be sufficient to mention here the forage experiments; although the experimental period has been necessarily short, conclusive results have nevertheless been obtained. *Robustine* is a substantial food that keeps well ; it is made of dried blood, and contains 8.8 % of digestible albumen, Calves will not eat it. The author adds that ruminants, as a general rule, have an aversion to foods containing blood (2).

The distilled and dried pulp of fruit (pomace powder), and dried maize-stalk meal were fed to milch cows; the former were readily eatem, but the animals would not touch the latter, or account of their burnt smell.

All the cattle ate fresh fruit pomace with avidity; but Emmenthal cheeses made from the milk of cows fed with this pulp had a curious flavour, and special notes on the subject were communicated to stock-breeders.

Wood-sawdust, known as *nemolin*, was refused, together with the other forages with which it was mixed.

The feeding experiments made with the by-products of milling (*bran* and *middlings* of which the authors give the analyses) from the same wheat, whether damped or not before grinding, confirmed the results obtained by Wiegner, which proves that it is impossible to determine with certainty whether grinding corn will increase the nutritive qualities of the by-products of milling.

---

(1) For Lehmann process, cf also Kellner, *Die Ernährung der Landw. Nutztiere*, Parey, Berlin, 1916, p. 281. For Beckmann's system, see Fingerling and Schmidt, "Die Strohaufschliessung nach dem Beckmann'schen Verfahren," in *Die Landw. Versuchs-Stationen*, Vol. 94, p. 115. Berlin, 1919.

Fingerling and Schmidt, from their experiments on sheep, conclude that the cold disintegration of straw under ordinary pressure, with a 1.5 % soda lye, as recommended by Beckmann, must continue at least for 1 ½ hours and preferably for 3 hours, if the maximum increase of digestibility is desired. Beckmann advises the process being continued for 2 hours. (*Ed.*)

(2) According to Kellner and Pott, this statement would seem incorrect (*Handbuch der tierischen Ernährung und der landw. Futtermittel*) 1909, Vol. III p. 515. (*Ed.*)

The *mixture of forage flour* composed of the by-products of milling and Dari flour, or that made from canary-grass (*Phalaris canariensis*), millet, and vetch (*Vicia Ervilia*) has no bad effects upon pigs, if fed cooked and immediately after cooking, at the rate of 0.7 kg. per head per day.

Colza and sunflower cakes from Rumania do no harm to cows, if given in the proportion of 1 kg. per head per day. Colza cake, when fed alone, was refused by the animals.

Poultry will eat 30 gm. of dry cockchafers (*Melolontha*, sp.) daily without any unpleasant taste being imparted to the eggs.

Cereal flour gives better results when dry than soaked, from the point of view of milk yield.

First-class Emmenthal cheese, when made from the milk of cows given moderate quantities of sesame cake and rye flour, showed no anomalies or defects.

No effect was produced by giving milch cows for 12 weeks 3 gm. of calcium chloride per quintal of live weight per day in their drinking-water. Seeing the good results obtained in Germany (1), the author concludes that further and longer experiments are necessary.

Special interest has been aroused in Switzerland as to the ensilage of green forage. While awaiting the general report to be given at the conclusion of the experiment with the *Herba* system, it may be said that, under certain conditions, it is a good means of increasing the gross return of meadows, and consequently extending the forage crops. Emmenthal cheese, however, can not be made from the milk of cows fed on ensilage.

During the war, improvements were made in LEHMANN's method of disintegrating straw by the alkaline process. The Chemical Laboratory of the Zurich Polytechnic advises that the straw, after having been boiled 6 hours in a caldron with alkaline soda, should be neutralised by the addition of a little sour whey. Feeding experiments made on pigs and cattle have shown that straw thus treated, though appetising and a suitable food, is not sufficient for young animals, unless albumen is added. The use of the system, which is best carried out on a large scale, is, however, subordinated to its cost. In another experiment, made at Liebefeld, with straw treated in the cold with caustic soda, and subsequently neutralised by the addition of ensilage, the mixture was eaten by the cows with avidity, though their milk was not suitable for cheese-making.

Other war forages were intended as substitutes for oats and hay, and consisted of fibre treated by the LEHMANN process, albuminoid and starchy substances being added. Experiments have shown that these substitutes were far from equalling the originals, but they should nevertheless be regarded as good supplementary foods in times of scarcity.

Another substitute for oats, known as *Sadhaco*, was not at all a favourite with cattle.

V. — During the war, more than half the usual oat rations of the French Army horses had to be replaced by substitutes. Horses, however, are more sensitive than any other animals to traces of poison which are present in plants and vary according to the conditions of their growth. Poisoning, moreover, is not the only danger threatened by substituting other substances for oats in the rations fed to horses.

---

(1) See *R*, 1918, No. 64. (*Ed.*)

Wheat and barley are cereals that suit horses very well. Barley used to be the sole food given to the horses of the Roman army, and horses in Africa and the East have nothing else (1). It is advisable, in order to render the awns innocouous, to cook or otherwise soften the barley, or also to crush it, but care must be taken not to reduce it to powder, for in this form it is injurious to horses.

As rye is never thoroughly masticated, it should be broken up or boiled. Great care must be used not to feed horses with rye that may be infected with ergot.

Maize has long been used; it should be crushed, but not made too fine.

Sorghum, which is imported into Marseilles under its Greek name of *Dari*, or the Egyptian ones of *Doora*, or *Doura* (2) is usually employed for distillation. The sorghum grown in Provence provides corn for the poultry-yard, but during the war it was crushed and fed successfully to horses.

Paddy was also used in the form of sharps, but in order to prevent rachitis, forages rich in lime were added, or else 15 gm of washed chalk per ration.

Molasses, like all foods containing sugar, is very good for horses, but they should not be given more than 2.5 kg. per head per day.

Tubers and roots were also dried for use as stock feeds. In Switzerland and Germany, potato flakes were prepared during the war, and *cossettes* of manioc were imported into France from Madagascar; these feeds have to be softened before use.

Carobs were used with great success in France for the Army horses, and replaced as much as ½ the grain ration. The pods were selected and pounded, all the seeds above 1 % being carefully removed. Whenever these precautions were neglected, bad and even fatal results ensued, owing to the obstruction of the intestines, and also, according to the author, to other undefined causes of which the quality of the fruit, its state of preservation, and its origin appeared to be the chief (3).

Oats were also partially and successfully replaced by groundnut cakes. They make an efficient substitute, but care must be taken to avoid those containing the smallest amount of ricin (4).

(1) This is also the case in Sicily (*Ed.*)

(2) According to some authors, *Dari* is a cultural variety of *Sorghum vulgare* which is called *Doura* by the Egyptians; according to other authorities (KELLNER, for instance) it is a distinct species, *Sorgum tartaricum* (See, POTT l. c. pp. 160 and 492. (*Ed.*)

(3) The necessity of crushing carob-pods is a vexed question. At Naples the cab-horses are given bran and whole carobs. See also *R.*, Dec., 1918 No. 1380, and *R.*, Jan., 1919, No. 80.

(4) It appears that the toxics properties of ricin can be removed by heating. See *R.*, June, 1920, No. 672. (*Ed.*)

Cacao pods, which had hitherto been given to ruminants, were also fed to horses during the war. The latter animals are, however, very susceptible to theobromine (1).

407 - Experiment in Breeding Goats with Supernumerary Horns, in Germany. — MULLER, R., in the *Deutsche Landwirtschaftliche Tierzucht*, Year XXV, No. 2, pp. 13-14. Hanover, January, 1921.

The author, in continuing his researches on the effect of in-breeding goats possessing supernumerary horns (the results of which he published in the *Zeitschrift für induktive Abstammungs- und Vererbungslehre*, 1912, Vol. III, Part. 3 (2), carried out some new experiments in 1913-1917, for the purpose of obtaining experimental proof of the accumulation of hereditary tendencies, and of the increased development of individual physical characters.

The male resulting from the first experiments had six roots of horns, two of which were fused together from birth. This animal was mated with:— (*a*) its mother; (*b*) its aunt; (*c*) its sister; (*d*) a daughter, the issue of the last mating. In spite of this very close blood-relationship the offspring never had more than four horns. Thinking that the cause of non-transmission was to be found in the loss of reproductive power of the male, which was the product of the union of brother and sister, the author proceeded to introduce some fresh blood by using a small, black-coated, male Angora hybrid.

The results of the different matings of this animal were as follows:—

(1) With a two-horned dark fawn-coloured goat (the mother of the six-horned male):— A male and a female with two horns, and one male with four horns.

(2) With a four-horned goat (sister of the male which, mated with the other dark fawn-coloured sister, produced a six-horned male; aunt of the latter):— One male and two females, all with four horns.

In order to increase the consanguinity, the male resulting from the mating of the four horned goat and the hybrid Angora he-goat was mated with one of its own sisters.

The offspring of this union was a white male possessing already shortly after birth, eight roots of horns, of which two fused, thus leaving only 5 to develop further.

The offspring resulting from mating a son of the hybrid male Angora with a two-horned goat, and that of the union of eight-horned male with related females, always showed an increase in the roots of the horns. The product of the union of the eight horned male and its mother was a kid with seven roots of horns; when the eight-horned male was mated with a related two-horned female, the offspring was a kid with 5 roots of horns.

According to the author, these results show that in-breeding preceeded by the introduction of fresh blood, brings out hereditary tendencies, and increases their power of development.

[406-407]

408 - **Heredity in Rabbits** (1). — VECCHI, A. (Zoological Institute of the University of Bologna), in *Natura*, Vol. XI, pp. 143-169, 4 fig., Bibliography of 16 works, Milan, 1920.

All authors admit she existence of two geographical races of the common European rabbit (*Oryctolagus cuniculus*), viz., the typical European breed (*O. c. cuniculus*) living in Northern Europe, and the British Isles; and the Mediterranean breed (*O. c. huxleyi*), found in the Mediterranean region.

The author passes in review preceding works dealing with the transmission of the characters of these two races and of their hybrids, and described his own experiments.

VARIATIONS IN SIZE IN TAME RABBITS AND THE TRANSMISSION OF THESE CHARACTERS. 1) There are two distinct types of rabbit characterised by the different proportion existing between the length of the tarsus and that of the body; 2) it is difficult, and perhaps even impossible, to distinguish races by their weight and dimensions, for these characters vary between two extremes, and present a series of intermediate variations (2); 3) it is probable that the giant breeds, especially the Flanders giant rabbit, are the result of crossing lop-eared rabbits with macropodous rabbits with normal ears because in the first place, the ears of the latter are always very long, and in the second, individuals are often born with one, or more rarely, two pendent ears, a defect showing the effect of the crossing with the lopeared rabbit.

THE COLOUR OF WILD RABBITS AND ITS FACTORS (3). — According to CASTLE, the wild grey rabbit owes its special hue to the existence of a chromogeneous substance (C) of 3 colours; yellow (L), brown (Ph), and black (M) distributed in a varied and determined manner on the hair of the upper parts of the body alone (Ly) and in a uniform manner (H), but so that the yellow of certain zones and of part of the coat has a limited extent (E). If the E factor is alsent, the black and brown colouring is confined to the eyes, or at most to the extremities, because the yellow is no longer limited to any particular part, and the whole coat is of that colour. Should the factor H be absent, the chromogene is no longer uniformly distributed, and the coat is spotted with white.

---

(1) See *R.*, Oct., 1915, No. 1060.

(2) The differences are explained, if we suppose (CUÉNOT, CASTLE), that the quantitative characters do not depend upon a single invariable factor, but rather upon an inconstant determinant, which produces reversible, quantitative variations.

On the other hand, NILSON-EHLE and JOHANNSEN, basing their opinion upon the hypothesis of the absolute constancy of the "genes," maintain that quantitative characters (both in animals and plants) do not depend upon a single determinant, but upon a group of independent factors (polymery) the dominance of which does not appear in the 1st generation. These factors are segregated in the 2nd generation, wich reduces the number of individuals resembling the parents (pure), through the increase of competing factors. In selection however, it would always be possible to separate stable combinations, and thus obtain pure, invariable lines. (*Author's Note*)

(3) See *R*, Oct-Dec. 1919, No. 1220. (*Ed.*)

The absence of the myochromogenous factor (My) permits of the mixture of the different colours, in which case the rabbit is entirely black, for between the colours yellow, brown, and black a kind of order of precedence exists, and black conceals brown.

If the pycnogenic, or intensity factor, P, is wanting, its opposite, p., weakens the colours, replacing black by blue and fawn-yellow by cream-yellow.

When the chromogene C is absent, the pigment disappears and the rabbit is entirely white.

The three other factors, the luteogenetic, phaeogenetic, and melanogenetic, respectively, are always present, even if the rabbit is white, but in the absence of the chromogenetic substance, they are suppressed

Colour transmission. — The factors present in the wild grey rabbit are all dominant as regards their negative antagonists. The grey colour of the wild rabbit is dominant in respect to all other colours. Black is dominant, as regards blue and yellow, and these colours combined produce the grey coat of the ordinary rabbit. All the colours are dominant as regards white.

There is still much uncertainly as to the importance to be attribute to the different coat-markings. It is, however, possible that the factor H that represents all these variations, may be replaced by many additional factors which are not transmissible according to the laws governing dominance, but depend upon fusion, in the same manner as the quantitative characters relating to size.

Transmission of length of coat — Long hair like that of the Angora rabbit, is recessive in crosses with shorthaired rabbits. Coat length is independent of colour. The character "length of coat" follows the Mendelian laws of dominance, segregation, and independence of characters, and can be correlated with any character of shape, size and colour.

The Author's experiments. — These extended over 4 years, from 1916 to 1920, and were concerned with the heredity of colour in crosses between blue St. Nicholas rabbits, and Himalayan rabbits, between St. Nicholas rabbits and Silver-Greys (*Cuniculus argenteus*), the colour and weight of hybrids from crosses between Giant Flemish rabbits and Japanese rabbits; finally experiments on telegony (1) furnished a new hypothesis respecting telegonic heredity.

The results obtained proved the truth of the conclusions reached by Castle and other workers, and show that the formula invented by Castle to represent the gametic constitution of the wild grey rabbit corresponds to a group of actually existing "genes". The present author, however, doubts whether this formula includes all the genes; for it does not account for the silver present in all the fundamental colours. There are, further, some favourite old breeds, like the Chinchilla, or modern ones, such as the Havana, of which the gametic formula is unknown. Many colour "genes" do not follow Mendelian laws of heredity, but are transmitted in an intermediate degree, and in a variable manner, *e. g.*, the spots usually found on Himalayan rabbit, stripes on a yellow ground, the particular arrangement of colours in the case of silver-grey rabbits.

---

(1) See *R*, July-Sept. 1919, No 930 (*Ed*)

What we known about the transmission of characters in rabbits enables us to state that the breeds, as defined by the respective standards, are nothing but conventional correlations of a certain determined number of fundamental characters. These, as compared with the wild rabbit are:— 1) Larger size; 2) greater length of tarsus in comparison to body-length; 3) long, pendent ears; 4) convex skull; 5) sub-jugular cutaneous fold (goitre of the Flemish rabbits); 6) long coat (Angora); 7) grey coloration; 8) uniform black coat; 9) uniform blue coat; 10) uniform yellow coat; 11) uniform white coat; 12) white spots; 13) coat with black spots on yellow ground; 14) coat spotted with white (silver); 15) coat with markings (Himalayan); 16) coat with dark black markings.

As many breeds of rabbits can be created as there are combinations between these characters, and the number could be still further increased, if variable characters were taken into account such as size, and new characters, like the Havana coat, of which the gametic formula is still unknown.

409 - **Effect of Excessive Use of Male Rabbits in Breeding.** — HAYS, F. A. (Wyoming Station), in *The Breedero Gazette*, Vol LXXXIX, No. 2-2040 p. 66. Chicago, Jan 13, 1921.

Report of experimnts with domestic rabbits at Iowa Station in 1916. Males usually performed 20 services at intervals of from 10 to 15 minutes.

Body weight and growth in body measurement were apparently in no way reduced by excessive breeding. The mortality rate in offspring does not increase with heavy breeding of te sire. The proportion of males to females seems, on the contrary, to be appreciaioy affected.

The table given shows that the sex ratio in the first service group was 129 males to 100 females, whilst the roth service group showed a ratio of 28 : 100. The same correlation evidently exists for the intermediary service groups (5th to 15th).

410 - **Results of Stallion Service at the German Stud Stations (Service Season 1919).** — MULLER, W., in the *Zeitschrift fur Gestütskunde*, Year XV, No. 10. Hanover, October 1920.

The author, as a result of questions sent to the various Stud Stations, obtained the following data respecting the Service Season of 1919 (See Table on page 448)

The figures given show that the number of unfertilised mares was very large in the Frederick-William Stud Station at Neustadt am/D. According to the author, this number of unfertilised animals could be reduced by subjecting suspected brood-mares to veterinary examination, and ascertaining by means of the microscope, the vitality of the spermatozoa of stallions which have served mares proving not to have been fertilised.

The figures referring to the fertilised mares are less accurate, on account of the omission to register the results obtained outside the Stud Station.

The statement made by the former «Oberlandstallmeister» VON OTTINGEN, as to the preponderance of colts over fillies appears to lack foundation. At Trakehnen, Graditz, and Beberbeck, unlike Neustadt, more females than males were born. The author proposes to study this question in the following years.

Chief Stud Stations.

	Trakehnen	Graditz	Beberbeck	Friederich Wilhem Stud Station	Total
Number of stallions	18	15	5	3	41
Number of mares served	362	215	108	70	755
Number of mares not registered	16 = 4 %	45 = 20.9 %	4 = 3.7 %	—	65 = 8.6 %
Unfertilised mares	99 = 28 %	73 = 33.9 %	30 = 68.6 %	36 = 51.4 %	238 = 31.5 %
Fertilised mares	247 = 68 %	97 = 45.2 %	74 = 68.6 %	34 = 48.6 %	452 = 59.9 %
Abortions	17 = 7 %	9 = 9.3 %	3 = 4 %	2 = 5.9 %	31 = 7 %
Twin births	2 = 0,8 %	1 = 1 %	—	—	3 = 0,7 %
Live foals	232	89	71	32	424
a) colts	110 = 47.4 %	43 = 48.3 %	31 = 43,7 %	18 = 56.3 %	202 = 47.6 %
b) fillies	122 = 52.6 %	46 = 51.7 %	40 = 56,3 %	14 = 43.7 %	222 = 52.4 %
Longest gestation period in case of colts (days)	354 days	360 days	354 days	348 days	354 days
Shortest gestation period in case of colts (days)	302 »	325 »	318 »	323 »	317 »
Average gestation period in case of colts (days)	337 »	342 »	340 »	334 »	338.5 »
Longest gestation period in case of fillies (days)	360 »	370 »	365 »	343 »	359.5 »
Shortest gestation period in case of fillies (days)	302 »	315 »	323 »	325 »	316 »
Average gestation period in case of fillies (days)	335 »	342 »	335 »	332 »	336 »
Number of animals bred that were kept at the stud station:					
a) station stallions	22	23	8	8	
b) brood-mares	10	25	12	11	
Number of horses rejected	—	76	10	33	

The great difference between the longest and shortest duration of the gestation period is most interesting; the causes of these differences are unknown (1).

The returns of the Stud Stations at Indenau (Brandenburg), Leubus (Silesia), Labes (Pomerania), Marienwerder (West Prussia), Wickrath (Rhine Provinces), as well as those of Redefin and Achselschwang, evidently cannot be correct, the information having been given by breeders. Nevertheless, here again, more female foals then male were stated to have been born.

---

(1) MIECKLOV, in *Zeitschrift für Gestütskunde*, Year XIV, No. 8, p. 126. (*Author's Note*) — See *R.*, May, 1920, No. 554. (*Ed.*)

411 - New Scale of Points for judging the Breeding Qualities of Show Cattle.— Schmidt, B., in the *Deutsche Landwirtschaftliche Tierzucht*, Year XXIV, No. 47, pp. 489-490. Hanover November, 1920.

On the occasion of the auction at the 23rd show held at Insterbourg in September, 1920, by the Herdbook Society of the Black Pied breed of Netherland cattle (Herdbuchverein für das schwarzweisse Tieflandrind) an entirely new scale of points was adopted in judging the animals entered, pedigree, shape, and milk-producting capacity being taken into consideration at the same time. The use of morphological characters as affording an index of milk-yielding aptitude was entirely abandoned, the actual milk yield of the female progenitors, as given by the records of societies for the registration of the performance of milch cows, being substituted for it.

As many as 9 points may be given for capacity for milk production, and the same number for type, coat, pedigree, general development and capacity for beef production.

Milk production up to 100 kg. of milk fat per annum only is taken into account. When the animals are of great value for breeding purposes, a higher capacity for milk production can be marked by giving additional points.

The method of scoring in detail is as follows:—

The breeding qualities of the cattle at the show were estimated by points; 36 points at the maximum can be credited to each animal; these are distributed as follows:—

(1) Type, coat, pedigree maximum point..	9
(2) Shape	9
(3) General development and beef-producing capacity (weight)	9
(4) Milk-producing capacity	9
Total	36 points

Meaning of the points in the score for capacity for milk production.

9 — very	Intermediate points will be given when required.
7 — good	
5 — fair	
3 — tolerably good	
1 — mediocre	
0 — very bad	

In judging bulls the performance of the mother as well as that of the other female progenitors are taken into consideration. The digestive capacity of the animals, on account of the impossibility of feeding them normally, was left out of consideration.

The number of points for capacity of milk production varies between 5 and 9, according to the fat content of the milk :—

5	points	for	60.0 — 69.9	kg.	of	fat
6	»	»	70 0 — 79.9	»	»	»
7	»	»	80 0 — 89 9	»	»	»
8	»	»	90.0 — 99.9	»	»	»
9	»	»	100 0 — and over, kg. of fat.			

Animals that can be credited with altogether more than 20 points for type, coat, and offspring, as well as for symmetry, general development, and capacity for beef production, can also be given 5 additional points for good capacity for milk production.

This points are distributed as follows:

10	points	for	110.0 — 119.9	»	»	»
11	»	»	120.0 — 129.9	»	»	»
12	»	»	130.0 — 139.9	»	»	»

These figures include the pre-war and post-war returns. The former are estimated separately at the Commissariat.

412 - Observations on the Correlation Between Length of Horns and Age in Young Cattle of the Brown Alpine Breed in Italy.

—BRENTANA, D., (Zootechnical Institute of the Veterinary College [*Scuola superiore*] of Parma), in the *Nuovo Ercolani*, Vol. XXV, Nos. 21-22, pp. 265-277. Turin, November 15-30, 1920.

It is well-known that a positive correlation exists between the length of the horns and that of the coat in cattle, and that, generally speaking, the horns are shorter in proportion to the earlier maturity of the breed.

The author gives a short summary of numerous works dealing with the factors influencing horn development in cattle, as well as of the researches of FAELLI, CORNEVIN and LESBRE, KRAEMER, MASCHERONI, PERGOLA and LESBRE, on the determination of the age of calves from the length of their horns (the above-mentioned writers do not all agree). He then gives data (see following Table) referring to calves of the brown Alpine breed, which were born at the Central Cattle Dépôt of the IV Army, of cows commandeered in the Province of Cremona and reared under similar conditions.

The data collected by the author show that the growth in length of the horns is not so regular that there is any exact correspondence between the age of calves and the length of their horns. Nevertheless, until about the 6th or 7th month, the variations in the average length are less than those occurring later. Therefore, the measurement of the horns may give approximate data for determining the age of the animals from 6-7 months old, after which time, the approximation continually decreases. The age of heifers is given correctly by the length of the horns in centimeters plus 2 ; that of bull-calves by the length of the horns in centimeters plus 1 (in the brown Alpine breed, the horn development is more rapid in the males than in the females). When the animals are over 2 months old, the following data may be used:— The bony protuberance which is the first sign of the appearance of the horn is perceptible beneath the skin towards the 15th day; after about 1 month, the nucleus of the horn appears, free from hair; when the calf is between 1½ and 2 months old, the small horns begin to grow.

The author has also observed that a larger circumference is connected with greater length of horn, and that, up to 18 months, the horns grow more in circumference than in length; when the calf is older, however, the reverse is the case.

Horn Development in Young Cattle of the Brown Alpine Breed.

Guernsey and Jersey breeds, with a view to testing the it value as regards increaseg in producing ability of the herd, (milk and butterfat).

The influence of good feed and care on the production of these animals was studied and also in breeding investigation, and results are shown in various Tables

A number of grade animals sired by purebred bulls (Holstein, Guernsey or Jersey) and descended from scrub cows was studied in 2 groups: the first generation grades, *i e.* those carrying 50 % of blood of one of the recognised dairy breeds, and the second generation grades *i. e* carrying 75 %.

FIRST GENERATION GRADES. — Purebred Holstein bull × scrub cow, showed in the first generation an increase over their dams in milk and butterfat production, with an average of 89 % in milk and 58 % in fat In the case of F_1. of Guernsey grade × scrub cow, the average increase in yield was 17 % in milk and 27 % in butterfat, and with Jersey grade × scrub cow, it was 22 % in milk and 34 % in fats

SECOND GENERATION GRADES. — The average increase in production for the second generation Holstein grades as compared with their scrub grand dams was 174 % in milk and 130 % in fat, In the case of Guernsey grades, 72 % in milk and 94 % in fat, and for Jersey second grades, 59 in milk and 74 % in fats

In the appended Table, the averages for two generations of grades and their scrub ancestors are givers.

The results obtained show clearly that the use of purebred sires is a sure way of increasing milk and butterfat production, if bred with a scrub herd, on condition that the bulls are selected carefully both fron the point of view of their heridity and also of their individual capacity.

414 – **Rearing Calves on Milk Substitutes** (1). — DECHAMBRE, in the *Comptes rendus des séances de l'Académie d'Agriculture de France*, Vol VII, No 6, pp 107-122, Paris, February, 9, 1921

The Animal Husbandry Section (*Section d'Economie des Animaux*) of the Academy of Agriculture of France requested the author to read a paper on the means of ensuring the proper feeding of young hand-reared calves without interfering with the milk supply required for human consumption or by the dairy industry. In this communication, the author describes the methods to be recommended, and which are at present in use.

Instead of feeding calves exclusively on milk, great economy can be effected by the use of various substitutes.

Of these the chief is skim milk, whether fed alone, or with the addition of suitable substances; its use promotes the consumption of farinaceous matters, grain, or similar foods. *Whey* from the cheese-factories, *hay tea*, and an *infusion of barley radicles* can also be fed, provided such nutritive and digestible substances are added as give the mixture the nutritive value of whole milk These liquids also serve to complete a ration containing farinaceous substances, grain, or seeds Calves are still reared on *mashes* consisting of various ingredients, and, finally, on suitable dry foods that are properly prepared and fed. Among the substitutes usually least known to practical agriculturists are *starch, manioca flour, rice flour, linseed, meat meal.*

---

A *diet of corrected skim milk is fed as follows:*— Giv · the calf whole milk for 15 days, then during a transition period of 8 to 10 days gradually introduce the corrected milk. If the calf takes readily to the change, a week is sufficient to accustom it to the new diet; should it suffer from diarrhoea, the mixed feeding must be continued longer. It is the task of the breeder to observe his young stock carefully, so as to know when to shorten or lenthen this transition period. The daily ration is calculated on the basis of 1 kg. of corrected milk per 6 kg. of live weight. At first, 3 meals are given, and after the 5th week only 2.

The whey from the factories where Gruyère and similar cheeses are made can be used for feeding calves. Care must be taken that it is not acid; provided the whey is fresh, it can begin to be fed from the first fortnight and given above after a fortnight of transitional feeding. Several complementary substances are added to the whey. Meat meal gives good results, as do also the flours of cereals, or crushed grain.

Hay tea is an infusion made by pouring 2 litres of boiling water on 1 kg. of good quality hay in a closed vessel. The infusion process shold last at least 6 hours if it is desired entirely to exhaust the hay; as a rule, however, it is only continued till the water becomes cold. Hay tea can also be prepared by soaking forage for about 12 hours in cold water. In this way, the water takes up twice as much nitrogenous matter as is dissolved by ordinary infusion. Although little practised this method is greatly to be recommended.

In feeding young calves reared by hand, hay-tea is most useful. It can be added to milk or mixed with flour, cooked roots, or other similar substances. As a basal liquid, it can take the place of skim millk in various preparations, or be used in addition to it.

Its use is highly to be recommended. In the region of Melun, in accordance with the advice of ROSSIGNOL, a veterinary surgeon calves have been reared on hay-tea since 1915 and 1916.

Infusion of barley-radicles. — If 15 litres of boiling water are poured on 1 kg. of barley germs, an infusion is obtained which can take the place of a daily ration of 4 to 5 litres of skim milk in feeding calves. It should be given progressively, beginning with 1 litre a day and increasing to 4 or 5 litres by the end of 1 month.

Mushes. — When all the milk of the cows is consumed, and there is no skim-milk, a liquid preparation of which the composition resembles as nearly as possible that of whole milk is fed to the calves. Amongst the different preparations used, the following may be mentioned as having yielded satisfactory results:—

Haricot Soup. — Boil the beans (*Phaseolus*) until they are quite soft, then pass them through a sieve. First use 100 gm. of beans to 2 litres of water, and increase the beans gradually, until the calf eats 0.5 kg. (divided into 2 meals) a day.

English Preparation No. 1.

Wheat flour	1	part
Linseed meal	1.5	parts
Ground linseed cake	2	parts

100 gm. in 3,5 litres of warm water to be fed per meal at first. Give 2 meals a day, and increase the amount gradually up to 200 gm.

English Preparation No. 2.

Linseed meal	2	parts
Oat meal	2	»
Ground linseed cake	1	part

Mix 500 gm. with 4 litres of hot water and leave it to infuse during the night. The following morning, take half the infusion, add sufficient water to make up about 3 litres, and also a little salt and 10 gm. of sugar Prepare the second meal in the same manner. Gradually increase the amount fed, up to 1 kg. of the mixture per day.

Ration prepared and used by Hayvard *of the Agricultural Station of Pennsylvania.*

Flour	30	parts
Coconut	25	»
Milk powder.	20	»
Linseed meal	10	»
Blood meal	2	»

Mix 250 gm. with 2 litres of hot water for one meal. Give 2 meals a day, increasing the amount progressively, as in the case of the English mixtures.

The only objection to be made to this recipe is that all the ingredients are not easily obtained on every farm.

Ration prepared and used by Linsey *at the Agricultural Station of Massachusetts.*

Ground oats	22	parts
Ground linseed cake	10	»
Maize flour	11	»
Various flours	5	»
Blood meal	1.5	»
Salt	0.5	»

The mixture is prepared by first adding a little cold water to the dry flours, followed by 6 litres of hot water per kg. of the farinaceous compounds. The amount to be given at first for each meal is 250 gm. in 3 litres of water.

All the rations mentioned should be fed warm, *i. e.*, at 35° to 38° C., and in perfectly clean vessels, the latter precaution being necessary to prevent diarrhoea.

Grain. — Amongst the cereals used in France and England for feeding hand-reared calves, oats take the first place.

Crushed or pounded oats are better than whole ones, so it appears from the experiments summarised by the author.

Experiments in feeding calves on skim-milk and oats were carried out in Ireland in 1918 and 1919 at 21 experiment centres, with a view to deciding whether it was better to add ground oats, or whole oats, to the skim milk.

Two lots of 70 calves consumed the same amount of food, the average daily increase in live weight being as follows for the 122 days the experiment lasted: —

Lot fed ground oats	0.607
» » whole »	0.597

The difference in the results is almost negligible, it was found, however, that it is difficult to accustom calves to whole oats, and that it is necessary to begin with a very small quantity (55 gm.) and to increase the amount gradually.

These experiments have also shown that the flour need not be cooked for the calves after the 5th or 6th week (average age 5 ½ weeks).

Much the same system exists in the United States as regards the use of cereals for hand-reared calves. The crushed maize and ground oats are given mixed with wheat bran according to different formulae: —

I. — 3 parts crushed maize, 1 part bran.

II. — 3 parts crushed maize, 1 part ground oats.

III. — 3 parts crushed maize, 1 part bran, 1 part ground oats, 1 part linseed meal.

IV. — 5 parts crushed maize, 1 part bran, 1 part ground oats, 1 part dried blood.

These mixtures were fed from the 2nd week, and the amount given daily increased progressively so as to reach 0.450 kg. and 0.500 kg. at the end of the 4th week. The increase is so regulated that within the 3rd month 1.5 kg. is fed per day.

IMPORTANT OBSERVATION. — When the diet includes skim milk and grain, the latter must never be mixed with the milk.

CONCLUSIONS. — Many preparations can be used as substitutes for milk in feeding hand-reared calves. Whenever skim milk can be obtained, it forms a basis which can easily be completed. Should it be unprocurable, hay tea can be used instead, or else one of the above-given recipes, the choice being determined by economy and the ease with which the ingredients can be obtained. The next point is to remember that absolute cleanliness is indispensable, not only in preparing and distributing the rations, but also in the utensils, mangers, stalls, and litter. Illness in hand-reared calves is frequently due, either directly or indirectly, to the lack of hygienic precautions.

In the discussion that followed the reading of this paper, H. SA-

GNIER mentioned that he had seen margarine used in Italy on a large scale for feeding calves as a substitute for the fat contained in skim milk.

DECHAMBRE stated that much skim milk was used in Italy; margarine and groundnut oil can be added to it, but a special apparatus is needed for making the emulsion.

Calves are reared on hay-tea in Normandy. It can be given alone, but it is better to add flour, ground oats, or linseed-meal (30 gm. per litre), or else crushed oats or linseed, which should be fed in a special manger.

415 - **Maize Stover Silage versus Maize Silage for Milk Production.** — MORRISON, E. B. HUMPHREY, G. C. and HULCE, R. S. in *Journal of Dairy Science*, Vol IV, No, 1, pp. 29-31. Baltimore, Jan. 1921.

Experiments made at Wisconsin Experimental Station, Madison, with 8 cows, producing an average of 1 ¼ lb. fat daily. They were separated into 2 equal groups, each being fed with two kinds of silage on the double reversal method for 2 periods each of 4 weeks duration with a preliminary week preceding each. The concentrate mixture used consisted of: 4 pts. ground maize + 4 pts. wheat bran + 1 pt. linseed meal + 1 pt. cottonseed meal and alfalfa hay fed at the rate of slightly less than 1 lb. of hay daily to each 100 lb. of cow weight. Each kind of silage was fed *ad libitum* twice daily. Apparently the cows consumed on an average about 5 lb. less stover silage daily per animal than of maize silage (33.25 lb. to 28.31 lb.).

Results indicated that the average daily milk production on the maize silage ration was about 3 lb. more daily per cow than on stover silage (27.4 to 24.5 lb.). A corresponding relationship existed also in the productions of butter fat (1.05 to 0.98 lb.).

Both lots lost to a certain extent in live-weight, but the difference is not great enough to be considered significant.

A comparison between the two silage rations from the financial standpoint, shows that the price at which stover silage could be figured was 61 % of the price at which maize silage was valued.

416 - **Observations and Researches on the Correlation Between the Yield in Blood, Hide, Meat, Fat, Bones, and Viscera, and the Live Weight, Sex, State of Nutrition, and Age of Cattle of the Brown Breed. in Italy.** — GIULIANI R., in *Clinica veterinaria.* Year XLIII, Nos 13-14, pp. 350-362, Nos. 15-16, pp. 410-430. Milan, July 15-30, August 15-31, 1920.

This is a contribution to the solution of the problem of how to determine, by classifiying cattle according to sex, state of nutrition and age, the average percentage of each of the products to be obtained when they are slaughtered. In order to get these averages, the observations have to be very numerous, as it is important to eliminate the factor of individuality.

The author begins by quoting other investigations similar to his own, and carried out by Messrs. LAWES and GILBERT, WOLFF, CORNEVIN, POLI, and DECHAMBRE (1). He goes on to describe the experiments made by himself at Monza using 90 animals divided into 5 classes: — (1) Manzette and heifers with 2 or 4 second incisors (20 head): (2) young steers with 2 or 4 second incisors (16 head); (3) bulls with 2 or 4 second incisors (15 head); (4) cows with at least, 6 second incisors (17 head); (5) oxen with at least 6 second incisors (22 head).

---

(1) Summarised in *R.*, March, 1918, No. 321 (*Ed.*).

After giving the data, which are collected in the appended table (where the percentages refer to 100 kg. of live-weight) the author examines them comparatively, and deduces the following conclusions: —

INFLUENCE OF THE STATE OF NUTRITION. — There is a clear connection between the state of the nutrition of the animals and the percentage yield in quarters, net meat, bones, fat, head, feet, stomachs and intestines. The 1st, 2nd. and 4th increase, and the others decrease with the improvement of the condition of the animals. On the other hand, there seems to be no connection between the condition of the animals on one hand, and the percentage yield of skin, liver, spleen, kidneys, lungs, and heart, on the other.

INFLUENCE OF SEX AND OF CASTRATION. — If a comparison is made between the data referring to animals in good condition (thus excluding any effect of the state of nutrition), and of 2 to 3 years of age (thus excluding the influence of age), it is found, that: — The *yield in skin, quarters*, and the *net yield of meat* are highest in the case of bulls, intermediate in that of young steers, and lowest in " manzette " and heifers.

The *yield in bone* reaches its maximum in young steers, and is larger in bulls than in " manzette ' and heifers.

The *proportion between net meat and bone* is higher in bulls than in " manzette " and heifers; in young steers it is lower than in the first and second; this fact is connected with the greater bone development in young oxen.

The *yield in fat* is considerably larger in " manzette " and heifers than in bulls; in young steers, the fat yield is almost the same as that in " manzette " and heifers.

The percentage weight of the head and feet is slightly larger in " manzette" and heifers than in bulls; in young steers it is considerably higher than in both the above mentioned classes of animals.

The percentage weight of the stomachs (without contents), of the *intestines* (with contents), of the *lungs, heart, liver, spleen,* and *kidneys* is higher in " manzette " and heifers than in bulls; in young steers, the weight, of these parts is about the same as in bulls.

THE INFLUENCE OF THE AGE AND DEVELOPMENT OF THE ANIMALS. — If the " manzette " and heifers are compared with the cows on the one hand, and young oxen with adu.t oxen on the other (so as to do away with the effect of sex and castration), the animals in both cases being in good condition (so as to eliminate the effect of the state of nutrition), it is found that: —

Cows, as compared with " manzette " and heifers, show a decrease in the percentage weight of the skin, head, feet and stomachs; and an increase in the percentage weight of the quarters, net meat, and bones (the proportion between meat and bone is about the same as in the " man-

zette"), whereas only negligible differences are shown in the percentage weight of the fat, lungs, heart, liver, spleen and kidneys.

In adult oxen there is, as compared with young oxen, a slight decrease in the percentage weight of the skin, quarters, net meat, and bones (the proportion between meat and bone being, however, a little higher) and the head; there is, however, a small increase in the percentage weight of fat, but the percentages of the various products show no great difference as regards young oxen and adult oxen.

THE INFLUENCE OF INDIVIDUALITY AND OF THE AMOUNT OF SOLID FOOD AND LIQUIDS INGESTED BY THE ANIMALS. — The members of the same group often show individual variation which should not be over looked. The animals that were the subjects of these experiments were slaughtered after fasting for 16 to 24 hours; in spite of this, the percentage weight of the stomachs with their contents varied between 10.82 and 26.06 % and that of the intestines between 2 and 5.32 %. These percentages will have more reason to vary if the animals have been slaughtered with their stomachs and intestines more or less full. instead of empty; and these variations would effect the percentage returns of the abattoir products. Therefore, in order to estimate the probable yield of cattle when slaughtered, it is necessary, to know whether they were fasting at the time and the length of time since they had been fed. If this cannot be ascertained directly, an approximate idea can be obtained by examining the plants and abdomen of the animal.

417 - **Sheep Breeding in Germany After the War.** — I. GOLF, A., in the *Illustrierte Landwirtschaftliche Zeitung*, Year 41, Nos. 85-86, pp. 374-376, figs. 4 Berlin, October, 1920. — II. KETTNER, in the *Deutsche Landwirtschaftliche Presse*, Year, 47, No. 9, p. 68. Berlin, January, 1920.

GOLF describes the present conditions of sheep-rearing in Germany, the measures to be taken for its development and encouragement, as well as the aim and methods of breeding to be adopted.

With the war, the economic condition of sheep-rearing improved. Forage was cultivated to a considerably larger extent, on account of the rise in wages, the agricultural worker's right to strike, and the scarcity of labour, so that most large farmers were driven to keep sheep, in order to use the supplies of forage which were two large to be consumed by the cattle, as owing to the above-mentioned reasons, there latter animals could not be kept in the same numbers as before the war.

In spite of the great shortage of shepherds, the number of sheep in Germany increased (within the frontiers of 1915), from 5 073 478 head in 1915, to 8 921 620 in 1919.

Of the average and small proprietors (according to the statistics of 1907), 51 % were, engaged in sheep-breeding, even before the war, and it is these persons (the owners of farms of less than 100 hectares) that should be encouraged and assisted to develop this industry.

According to the author, the best means of attaining this object would be to create *Syndical Sheep Farms* (Genossenschaftsschäfereien "), or more strictly *Sheep-Grazing Syndicates* (" Schafweidegenossenschaften "), such as have sprung up especially in the Provinces of Hanover and Brandenburg, and represent a method of sheep-keeping similar to but more up to date than, the *communal* system. Several proprietors unite to provide a collective flock of from 200-300 animals, and hire a shepherd, who is partly paid for his services, but may be allowed to share in the profits, or even keep a certain number of sheep himself, as is generally the practice in communal sheep-farms.

During the winter, each owner takes back his animals, the flock being made up afresh in the spring.

According to KETTNER, such Sheep-Grazing Syndicates have recently been formed in Silesia, and are the first of the kind in all West Germany. These Syndicates propose to keep their sheep (which are of the improved Wurtemberg breed) in the open, night and day, in order not to lessen their resistance to cold and disease. The Syndicates are Joint Stock Limited Liability Companies based on the following regulations :—

(1) For each animal the owner pays the sum of 10 *marks*, and caution-money amounting to 20 *marks*.

(2) The object of the syndicate is the improvement and development of sheep-breeding by the following means :—

(*a*) The engagement of a common shepherd.

(*b*) The acquisition of good animals for breeding and especially of the services of a first-class ram.

(*c*) Increasing the pasturage by making and renting grazing-grounds.

(*d*) The collection and common use of the subsidies granted by the Chambers of Agriculture, or other Agricultural Corporations.

(*e*) The co-operative sale of wool and other products.

(3) Any person can become a member, who undertakes to pay his assessed share of the expenses.

(4) Sheep-owners, who for good reasons, are unable to join the syndicate, can obtain grazing-rights by paying a certain reasonable sum.

As regards the objects aimed at in breeding, GOLF states that, at the present time, there is a marked tendency among breeders to raise dual-purpose sheep, that is to say, animals combining the highest possible wool yield, with mutton production, as such sheep are by far the most profitable.

The author divides into 4 classes the different methods of breeding, and the various races that are of value for the improvement of sheep-breeding in Germany: —

(1) Silky merinos, producing:
  (*a*) carding-wool and wool for woollen stuffs.
  (*b*) combing-wool, extra-fine, fine (AA-A).
(2) Early-maturity Merinos (merinofleischschaf) and Anglo-Merinos.
(3) Early-maturity varieties (black-faced) sheep (Schwarzköpfide Fleischschafe) of English origin.
(4) Local breeds.

The breeds in which sheep-rearers are at present most interested are the *early-maturity Merinos*, and the *local breeds*. The former are much valued on account of the satisfactory weight of their unwashed fleece (Schurgewicht), their long, soft (fineness A B) combing-wool, their early maturity, symmetry, and thriftiness, as well as for their excellent constitution. The local breeds are chiefly suited to the small or average farm where the owner takes up sheep-rearing without having had any prevoius experience in breeding. The *Dishley Merinos* and *Meleschaf* breeds are much liked ad widely kept for the sake of their extraordinary early maturity and their fattening capacity, as are early black-faced varieties of English origin, such as Shropshires, Hampshires, Oxfordshires and Suffolks which are also noted for the production of fat lambs (either pure-bred animals, or hybrids resulting from the cross black-faced ram Merino, but their wool is inferior, both as regards quantity and quality. This defect is very remarkable, seeing, that wool production is the most important factor at the present day. The former sheep only yield wool of quality B or B-C (intermediate or intermediate ordinary) and the wool of the latter is only grade C (ordinary quality).

As for the *silky Merinos*, their number is constantly declining and it is only in the Provinces east of the Elbe, that they form any considerable part of the total number of sheep. The author draws attention to the fact that they are good wool producing animals which is a matter of great importance, seeing that the increasing importation of foreign wool will particularly affect the sale of the ordinary local products

In conclusion, the author touches upon the necessity of a certain uniformity in the breeding-methods adopted in the larger regions. He advocates the institution of a National Sheep-Breeding Society, (Landesschafzucht) and the establishment, by the members, of Cooperative Wool-Collecting Centres (Bezirkssammrestellen) in the various States. These measures would insure an abundant supply of even-quality wool, and would provide the owners of small and average-size sheep-farms with a good market for their produce.

418 - **Sheep and Goat-Breeding and the Skin Trade in Brazil.** — Guedes M in *Chacaras e Quintaes*, Year XII, No. 1 pp. 29 30, fig. 1 São Paulo, January 15, 1921.

Brazil possess vast tracts of land eminently suitable for grazing-grounds. One of these is the zone of over 1 million sq km. extending from the State of Bahia over the greater part of Maranhão. It appears that sheep and goats do best in the southern part of this region

The sheep of the northern portion, which were introduced at the time of the discovery of the country have hardly any wool, and the little they produce is not used industrially. Goat-breeding is, however, a matter of considerable importance; it is generally practised by small proprietors, and needs but little attention. The herd is sent out in the morning to graze, and the animals, find there own way back in the evening to the folds. The skins of these goats are of excellent quality. They are not salted, but are soaked in a preserving solution, and dried in the sun They generally go through two intermediate stages before being sold to the exporting firms.

According to the latest available statistics, the number of goat-skins and fleeces exported from Brazil in 1919 were as follows:—

Goat-Skins and Fleeces Exported from Brazil in 1919.

	Quantity in kg	Value in *milreis*
Pará	161 423	593 819
Maranhão	16 425	54 751
Ilha do Cajueiro	16 425	342 172
Fortaleza	1 139 273	12 017 180
Natal	88 148	1 035 542
Cabedello	281 791	3 142 745
Recife	968 761	10 114 253
Maceió	64 226	586 587
Bahia	1 951 185	19 988 715
Rio de Janeiro	210 342	2 216 344
Other ports	244 974	984 925
Totales	**5 165 840**	**51 077 015**

Most of these figures refer to goat-skins, sheep-fleeces being exported in smaller numbers. Hides are also exported (in 1917 190 184 kg. of the value of 620 386 *milreis*). The author estimates that the production and exportation of hides from Brazil could easily be increased tenfold. He states that it pays better to export hides than leather of which equally large amounts are produced in Brazil.

419 - **Feeding and Weight of Young Pigs of the Large White Breed in Italy.** — GIULIANI, R. (Director of the Zootechnical Station of Latium, Rome), in *Il Coltivatore*, Year LXVI, No. 36, pp. 973-975. Casale Monferrato, December 30, 1920.

With a view to determining the connection between increase in weight and food consumption in the Large White Yorkshire breed of pigs, the author ascertained for 64 days from the time of weaning, the increase in weight of a farrow of young Yorkshire pigs, which consisted of 6 males and 6 females. The data obtained are given in the appended tables.

Increase in Weight.

		Males	Females
Total initial weight	kg	110 600	107.800
Total final weight	»	206 000	209.200
Total increase in weight in 64 days	»	95.400	101 400
Average increase in weight per head per day	»	0.248	0 264

Total Amount of Food Consumed by the 12 pigs in 46 days.

	Weight in kg.	Starch value
Wheat shorts	860	387
Maize flour	82	66
Barley meal	24	16
Beets	640	40
Lucerne	242	21
	—	530

Thus, with a consumption of food amounting to 530 starch units, an increase of 196.8 kg. in live-weight was obtained, that is, 269 starch values would be necessary to produce an increase of 100 kg. in live weight.

420 - **Experiments on the Feeding of Hens with Rations without Grain.** — WINNINGER, G., in the *Deutsche Landwirtschaftliche Geflügelzeitung*, Year XXIII, No. 18, pp. 497-498. Berlin, Feb, 1921.

I. — RATIONS WITHOUT GRAIN. — For a whole year 100 Italian hens (hens and pullets 2 years old) were fed on rations which contained no grain. The daily ration was 10 gm. of bone flour, 40 gm. lucerne, 30 gm. weeds, 20 gm. kitchen offal and 30 gm. sorb-apples. These materials were covered with boiling water and given as a mash on the next day. The hens were allowed to run free. It was found that 62 hens continued to lay, but the production showed a decrease of 56 % as compared with the preceding year, when the production was 120 eggs. After at least 30 gm. of grain had been added to the ration for 3 weeks, laying became normal. A second test with 50 hens gave the same result, and production was never more than 6-8 eggs day. Chemical analysis showed that the lack of grain had no remarkable effect upon the composition of the eggs ; it was observed, however, that the amount of vitamine was less.

II. — RATIONS IN WHICH ANIMAL SUBSTANCES WERE SUBSTITUTED FOR GRAIN. — As grain is relatively rich in vitamines, the author attemted to replace them by food of animal origin which contained a relatively large quantity of amides. The 19 hens experimented with, laid 4-5 eggs a day when the grainless ration was given, but the production increased as the quantity of meat meal was increased.

When the quantity of meat meal was increased from 10-60 gm. during the period Feb. 1-July 21 the egg production increased as follows :

10	gm. of meat	flour	per day	6	eggs.
20	»	»	»	10	»
30	»	»	»	13	»
35	»	»	»	14	»
40	»	»	»	15	»
50	»	»	»	15	»
60	»	»	»	18	»

The total production during this period was 1368 eggs, giving an average of 72 eggs per hen in 172 days. The maximum daily production was attained during the period March 31-April 18, with 60 gm. of meat flour, the production being 345 eggs, an average of 18 eggs. In addition, during this period, 12 hens each laid 2 eggs, so that one hen therefore produced 35 eggs during April. The author considers that this result was due to the meat meal.

In summarising the results of his experiments, the author remarks that even though the grain can be replaced by fairly large amounts of meat meal the best results would be obtained with rations containing 30 gm. of grain and 15-205 gm. of meat meal.

421* - **The Hemipteron *Lyryocoris campestris*, a New Parasite of the Silkworm recorded in Italy.** — *L'Italia vinicola ed agraria*, Year XI, No. 12, p. 188. Casalmonferrato, March 20, 1921.

In 1920, on several silkworm farms at Tezze di San Dona di Piave (Province of Venice) the recently-hatched larvae were attacked by an insect which Prof. CORTI, of the University of Bologna, has identified as the hemipteron *Lyrtocoris campestris* Torh., which lives on poplar trunks, under fallen leaves, etc.

This insect rapidly and repeatedly pierces the worm in the inferior lateral regions. The worm at first reacts with violent movements and then dies. The habits of this hemipteron are now being inquired into and means of control are being investigated.

422 - **The Intensive Culture of Carp at Morimondo (District of Abiategrasso, Province of Milan).**

— Tagliabue, C., in the *Bollettino della Società Lombarda per la Pesca e l'Acquicoltura*, Year XIV, Nos. 1-2, pp. 11-13., Milan, Jan.-Feb., 1921.

The land chosen for breeding Galician mirror-carp was in the centre of a rice field, and was divided into three plots of a total area of about 1000 sq. metres ; it was sown as meadow land and kept dry.

The following operations were carried out :—

May 2 1920 — Mowing of herbage that had grown in the dry ponds.
» 6 » — Filling of the ponds with water and immersion of the parents (1 female and 2 males per pond).
» 8 » — Spawning of the carp.
» 9 » — Removal of the adults.
» 14 » — Fry hatch out.
» 15-17 1920 — Fry were removed (about 60 000) and put to grow among the rice plants.

The temperature of the water in the ponds on the day before spawning was :—

18° C. at 6 a. m.	28° C. at 2 p. m.
20° C. » 8 »	28° C. » 4 »
22° C. » 10 »	27° C. » 6 »
26° C. » 12 »	24° C. » 8 »

On June 9, the ponds were completely drained and about 10 000 young carp, 2-3 cm. long, were removed and placed in other rice fields. Of this number 2.000 were preserved in fishponds, the intention being to put them back later into the same ponds after they had been refilled with water. At the same time the rice had been transplanted in the spawning ponds at intervals of 15 cm. along and 20 cm. between the lines.

The 2 000 young carp were fed successively with specially cooked cakes of maize flour, rice residues, blood meal, Canadian elodea, calcium carbonate, calcium phosphate and molasses.

The total amount distributed was :—

42 kg. of maize flour	at *lire*	0.80	per kg. =	33.60 *lire*
37 » rice husk	» »	0.30	»	11.10 »
30 » small rice	» »	0.60	»	18,00 »
8 » blood meal	» »	1.00	»	8.00
35 » Canadian elodium	» »	0.05	»	1.75 »
2 » calcium carbonate	» »	0.45	»	0.90 »
2 » calcium phosphate	» »	6.00	»	12.00 »
4 » molasses	» »	2.65	»	10.60 »
				95.95 *lire*

Cost of cooking: 75 kg. of wood at 0.18 *lire* per kg	13.15 *lire*
Manual labour carried out by children	20.00 »
Value of young carp when immersed	10.00 »
	139.10 »

1374 young carp, year old, total weight 40 kg. (average of each 29.5 gm) at 20 *lire* per 100	274.80 *lire*
less expenses	139 10 »
	135,70 »

Net profit 1357 *lire* per hectare.
Gross receipts from marketable fish:

40 kg. of young carp at 6 *lire* per kg.	240.00 *lire*
less total cost	139.10 »
Net profit	**100.90** »

or 1009 *lire* per hectare.

In this account the value of the young carp born in the ponds and afterwards put in the rice fields has been neglected, nor has the value of the rice crop, which was, in proportion, superior to that of the neighbouring rice fields, been included.

There are many other kinds of produce which may be used for feeding fish, such as lupin flour, crushed maize stalks, etc. Carp can also be given slaughter-house blood, either fresh or lightly cooked on a water-bath. Also numerous insects which abound in the soil and in stagnant water such as the worms found in rich soil, or planorbis or limnæa, which can easily be found in the rice-fields. By this means artificial feeding can be reduced and even completely eliminated.

423 - **Rainbow Trout in the Small Lakes of the Emilian Apennines** — *Rassegna di Pesca*, No 1-4, p. 120; *Bollettino della Società Lombarda per la Pesca e l'Acquicoltura*, Year XIII, No. 9, pp. 92-94 Milan, Sept., 1920

The rainbow trout (*Salmo irideus*) was introduced into Italian waters several years ago; it combines the advantage of rapid growth with that of remarkable vigour. It is the latter quality which enables it to live in warmer and more troubled waters than those where the native river trout (*Salmo fario*) are found. It was formerly believed that the habits of the rainbow trout were different from those of *S. fario*; that is why the fry were placed in rivers whose higher average temperature and less clear water were not suited to the native trout.

The idea that it was best to rear native trout in clear, cold waters and the rainbow in warm, and often muddy waters was abandoned when it was found that this trout did very well in the clear and cold waters of certain small lakes. PAOLUCCI announced, in 1915, that the rainbow trout was quite well acclimatised to the water of Lake Moncenisio, which lies at an altitude of 2 000 metres.

Some time later (*Annali di Idrobiologia e di Pesca*, vol. I, 1918), he published an account of the excellent results which he had obtained with the rainbow trout in some of the small lakes of the Emilian Apennines, *i. e.*, lakes Santo and Gemelli, or Lagni, situated, respectively, at 1 507 and more than 1 320 metres of altitude, lakes that freeze in the winter from a minimum of 3 to a maximum of 6 or 7 months. Not only has the rainbow trout become acclimatised but it is has reproduced in Lake Calamone (Reggian Apennines), situated at an altitude of 1407 metres, but which does not freeze because it is fed by springs.

The first *Salmo irideus* fry were put into this lake by the Piscicultural Station of Castelnuovo Monti on April 30, 1911. In the summer of 1918, adult trout weighing 0.5-1.5 kg. and also young trout 10-12 cm. long were caught; the latter were evidently born during the spring of the preceding year. This example, which appears to be the first of its kind in Italy, shows that it is quite possible to stock many of the small Apennine lakes, which are now quite void of fish.

FARM ENGINEERING

424 - **The Economic Advantages of Mechanical Ploughing** (1). — SCHWANECKE, H. Die Kraftpflüge und ihre Betriebskosten, in the *Mitteilungen der Deutschen Landwirtschafts-Gesellschaft*, Year 36, No 6, pp 90-97. Berlin, Feb. 5, 1921. — II. AMBROSINI, I., In tema di costo di aratura, in the *Giornale di Agricoltura della Domenica*, Year 31, No. 8, p. 58. Piacenza, Febr. 20, 1921. — III. BEGLINGER H., Entwicklung und Stand des Motorpflugwesens in der Schweiz, in the *Landwirtschaftliches Jahrbuch der Schweiz*, Year 34. No. 3, pp. 210-243 + 22 figs. + 3 plates. Lucerne, 1920. — V. LARUE, P., Notes de motoculture, in *La Vie agricole et rurale*, Year 10, Vol. XVIII, No. 9, p. 136. Paris, Feb. 28, 1921. — VI. HUFFEL, G., Emploi de tracteurs à chenilles dans les exploitations forestières, in the *Revue des Eaux et Forêts*, Vol. 59, No. 2, p. 40. Paris, Feb. 1, 1921.

I. — MECHANICAL PLOUGHS AND COST OF WORKING. — The question as to the economic advantage of mechanical over animal-drawn ploughs has been asked for several years now.

In 1908, Germany had 4 or 5 works making FOWLER ploughing sets but of the 478 machines then existing in Prussia, 67 % were of British manufacture, and generally had a locomotive of 16HP nominal. In Germany, the FOWLER steam ploughing sets were used on less than 0,12 % of the farms of less than 100 hectares in area, on 8.6 % of farms of 100-400 hectares and on 32.6 % of the farms of over 1000 hectares Electric ploughing is still little known, but internal-combustion motor ploughs are well known, being rope drawn, or by direct or indirect traction. These in turn gave place to automobile ploughs (" Tragpflüge ") and to tractors. Germany has mostly turned out direct-traction ploughs because, out of the 3 or 5 types of windlass ploughs, only one has proved at all popular. There are 14 or 15 types of motorploughs and about

---

(1) See *R.*, Feb. 1920., No. 244. (*Ed.*)

20 types of tractors, the latter being preferred nowadays. During the war, chain-track tractors have become perfected and made of practical use; there are 3 or 4 types of these in Germany. The replacement of the share and mould-board by a rotary apparatus has been tried. Since the war, light tractors, of 4HP or even less, have mostly been built, as they are useful in many ways; these machines are coming into vogue in America, as was seen at the Agricultural Week show held at Chartres in October, 1920. MEYENBURG reports tha. in America, 116 firms are building about 120 types of tractor, or about 170 different machines, taking account of the various sizes, and the number is still increasing. The perfect ploughing machine, however, has not yet been invented, if ever it will be.

It is impossible to say, under the present state of agricultural science and practice, what is the best, simplest, and cheapest way of ploughing, at any rate as regards Germany and Central Europe.

Apart from the question as to whether the present system of ploughing is the best, it is, at present, only possible to discuss the relative values of the different types. The plough share may be compared with the rotary-tillage machine, or with the cable-drawn, steam, internal combustion, or electrically driven ploughs of various sizes. Whether the ancient plough-share should be replaced by the modern rotary machine is not yet clear. If the soil is light and not stony, the rotary machine gives good service in breaking up hard land; again for peat and pasture land it seems the best and fastest implement, but it is not suited to stony, heavy, mineral soils. According to the author the best machine of this type to day is the " Landbaumotor " LANZ-KÖSZEGI Agricultural Motor which weighs 5 500 kg., and has a 4 cylinder 80 HP. engine. It can plough 4-8 hectares per day with a consumption of 150-180 kg. of benzine. This machine, with the plough removed, can be used as a tractor.

The MEYENBURG electric plough may become the true small plough, the chief tool of market and other gardeners.

The funicular or rope drawn plough is better than the direct traction plough, because it runs over but a small area of the field, and does not move away during ploughing; it is, above all others, independant of weather and soil conditions, it is faster and less liable to breakages. The disadvantages are the high price, due to its limited use, and the fact that the factories prefer to make heavy machine, the great weight and the need for more attention. For small farms, progress needs to be made with the single motor system.

The question of the type of driving power best suited to ploughing is very interesting. Electricity has many advantages, but is very costly, and the electric plough is still imperfect, but it should make great strides, especially as regards small ploughs provided with rotary members.

The author, after consideration of the pros and cons of steam ploughs, concludes in their favour. Internal combustion engined ploughs are not as suitable as steam ploughs chiefly because of the dirt they gather and the wear they suffer during ploughing. Again the fuel and oil is not always easily available and is not pure enough for perfect working, a most important point as regards the explosion engine (1).

Again, difficulties with the cooling system, magneto, and sparking plugs, and extreme wear of certain parts are all absent in the steam engine, so that the choice of a driver for a motor plough is of the greatest importance. According to REZEK, the fuel consumption of motor ploughs varies little per hour, whereas that per unit area may vary greatly, even with careful handling. Moreover, although machines of the same make and power will cover approximately the same area (*e. g.*, STOCK and KOMNICK) ploughed under equal conditions and in soils of average resistance (*e. g.*, 30-34 kg. per sq. dm.), they behave very differently in very light or very heavy soils, which is the reason for the very diverse opinions of practical men.

With regard to the dimensions of the machines the author thinks that steam engines of 12-14 nominal H.P. are the most economical, for average-sized farms, and 100-120 H.P. engines for hire. He estimates that the economy of using motor-ploughs of less than 20-25 H.P. (2) is doubtful, and if one favours a motor plough he advises, for large farms, not the machine of 100 H.P. or more, but several average machines of 50-60 H.P.

As for the quality of the work, the cable-drawn plough gives perfect results, even better than animal drawn ploughs Tractor and motor ploughs are correspondingly inferior to animal haulage.

The influence of mechanical ploughing on crop yield, and on the number of men and animals employed varies in each case.

The author concludes that in farms where motor ploughs are used, the elimination of an equivalent number of draught animals especially horses, occurs much more rarely than in farms that employ steam ploughs (3). The author analyses the capital invested and the cost of working, and concludes that, in 1907-1913, the daily cost of a two-horse team, driver included, could be taken at an average of 12 *marks*, so that the total cost of covering (hectare of sown land (average soil), under, normal conditions 16-22 cm. deep) cost 27 marks and ploughing under similar conditions 35-40 cm. deep cost 50 *marks* or more. The steam engine under the same conditions cost 13-25 and 18-40 *marks*, respectively (15-22 *marks* with the big machine used for 100 working days per year). In 1913, a 40 H.P. motorplough cost about 17 *marks* per hectare at a depth of 20 cm., and 20 *marks* at 30 cm. deep. If, in spite of all its faults, the mechanical plough was economical in use before the war, now it should be all the more so. The author quotes data to illustrate this regarding a 400-hectare farm with different systems of cultivation and ploughing, and shows that, in Germany, the present cost of animal ploughing of 1 hectare, at 16-22 cm. deep in average soil, is 300 *marks*, and at 35-40 cm. is 520 *marks*, whilst under normal conditions, ploughing mechanically 16-22 cm. deep entails the following cost:—

---

(1) The high price of benzine, paraffin, and heavy oils has suggested the use of poor gas for motor-cultivators. See *Journal d'Agriculture pratique*. Year 84, Vol. I, Nos 15 and 18. (*Ed.*)

(2) Recent motor shows mark the tendency, according to DUVAL, to increase the angular speed and the power; nowadays the average power is 30-40 B H. P. See the *Journal d'Agriculture pratique*, l. c., No. 6, p. 112. (*Ed*)

(3) An enquiry made in Pennsylvania showed that 57 % of the farmers had done away with their horses and that a tractor, working a constant area, replaced 4 horses. See *U. S. Department of Agriculture, Farmers' Bulletin* 1035, p. 32. Washington, 1919. (*Ed.*)

275-280 *marks* with tractors and motor-ploughs.
250 *marks* with cable-drawn ploughs (2 engines).
180 *marks* with twin-engined steam ploughs.

These results vary greatly with change of conditions.

CONCLUSIONS. — 1) All the mechanical ploughs examined with reregard to working cost are superior to animal ploughs. However, as regards safe working and good work the cable-drawn set can at least be put on a par with animal ploughing.

2) The steam ploughing set is to-day decidedly superior to the other types of mechanical plough, not only because of its safety, but especially for its cheapness, for it does not matter how small the field or how badly situated, as long as the machine is worked at least 30 days in the year. As the cost of a set is very great, it would be a great advantage to let one out on hire,or run it on co-operative lines.

II. — IS MOTOR-CULTIVATION STILL ADVANTAGEOUS? — The variations which have taken place lately in the price of animals and fuel have brought up this question again in certain parts of Italy (1). The author gives an example from the province of Piacenza.

Farm 80 hectares, in area, soil compact; during 9 years the rotation was:— 1) Maize; 2) wheat; 3) 4), 5) lucerne; 6) beet; 7) wheat; 8) trefoil; 9) wheat.

(a) *Before the introduction of the tractor*, the animals kept were, 12 draught oxen, 30 milch cows, 30 stock cattle and 8 horses.

(b) *After the introduction of the tractor:* 4 oxen, 38 cows, 30 stock cattle, and 8 horses.

When examining the variation under (*a*) and (*b*) the author took into account the interest on capital, cost of amortisation, accidents, repairs, etc., food and fuel, manual-labour and numerous other factors and he concluded that *the advantage of using a tractor is still considerable*, and as the advantage is so marked it can be presumed that some advantage will always remain to the tractor, provided no fundamental differences occur, even when allowance is made for the good will of the workers, for the fact that the tractor enables the best time to be chosen for the work, and is independent of epizootic diseases, strikes, drought, and the round of hired machines. It is for this last reason that the farmer prefers to buy his own tractor even where steam ploughing sets can be hired, in spite of all its advantages.

---

(1) In France also, there is almost a crisis in motor-cultivation, owing to the excessive price of benzine. See *Le phosphate et les engrais chimiques*, Year 30, No. 1326, p. 69. Paris, Feb., 1921. (*Ed.*)

III. — COMPARATIVE COST OF HORSES, OXEN, AND TRACTORS. — The author has taken into account in this calculation the cost of fodder, amortisation, cost of shoeing, wear of harness, interest on capital, unforseen occurrences, etc. and deduces a cost of 25 fr. per day per horse and 16 fr. per ox.

A tractor costing 21 000 fr. amortisable in 3 years, which works 150 days a year, costs 260 fr. daily. Therefore the cost of ploughing 1 hectare of land 20 cm. deep at the beginning of 1920 at Bertrandfosse. France, was :—

187.50 fr. with a 3—horse team
192.00 fr. » » 4—horse »
173.00 fr. » » tractor.

The author has come to the conclusion that, inspite of the disadvantages of the tractor, its mechanical kilogrammetric economy compared with the work of the animal motor is clearly established (1).

IV. — THE DEVELOPMENT AND SITUATION OF MOTOR-PLOUGHING IN SWITZERLAND. — The author (late chief of " motolabour an Commissariat pour la culture des places d'armes suisses pendant la guerre) places the appearance of the first motor-mower in Switzerland in 1913-1914. Towards 1916 the first tractor, the Mogul appeared, whilst the second, the Moline, appeared in the spring of 1917.

The first motor-plough test took place at Witzwil, near Berne, on Feb. 14-16, 1918. To-day there are several types in use in Switzerland, both of foreign and national make, but on account of the extent to which local property is divided, small 4-cylinder 16-20 H.P. tractors are preferred.

The first swiss tractor was built by SAUER of Arbon, whilst the firm of OTT built the plough. The combination, made its first appearance at Witzwil.

The author also reported on the constructional School and the tests used. It will be sufficient to describe a few tests on drainage and ploughing with turn-wrest ploughs.

For drainage a SCHEUZER chain-track tractor was used, drawing a ditcher or " *autodrainneuse* ". Engine 45 H.P., speed 4 km. per hour ; weight 6000 kg., width of ditches 35, 50, 80 cm. maximum depth 2.30 metres ; digging capacity 50-70 metres per hour at 1.5 metres deep. The ground was marshy, and after ditching, the tractor ploughed the same land. This tractor, according to the author is the only one capable of breaking up the land of the Rhône plains.

In the summer of 1919, an international competition was held, under the patronage of the Division d'Agriculture, at which a prize of 5 000 fr. was offered for a turn wrest tractor plough capable of digging at least two furrows at once. The official competition was held on March 25,

---

(1) The Pennsylvanian enquiries (see preceding note) showed that a tractor had a life of 9 years, and that the cost per day fell to 63.34 fr., and the cost per hectare exclusive of the wear of the plough, was 30 fr. See the continuation of this article. (*Ed.*)

1920 at Valentin, near Yverdon, between the only two double mould-board Swiss ploughs (OTTO and VOGEL). French and German firms were unable to send their machines on account of transport difficulties.

The tests were successful, but further progress is still required. These double mould-board ploughs which can be drawn by tractors, are a necessity for small holdings, for work on hill slopes (1), and for ridging. The author thinks that a balance plough could be tried, partly pushed and partly drawn by the tractor.

The author gives the list of motors used by the Commissariat Suisse during the war, together with their characteristics. He has calculated the cost of mechanical ploughing but states that it is impossible to carry out a proper scheme or to obtain accurate results with short and hasty tests. He cites all the factors on which he judged the cost of working animal and mechanical motors, and gives the following Table which shows the cost of working of each make of tractor used by the Commisariat, including the cost of repairs, salaries, depreciation, etc.

	Fuel Consumption Litres per hectare	Working Cost Fr. per hectare
I. — *Berna Tractor* Hired out in 1918-1919 at 30-50 frs per day		
a) Long road distances, ground moist, little adhesion, small areas	57.64	133.25
b) Peaty soil; wheels slipped	52.22	125 00
c) Good soil; engine running badly	50.70	126 40
d) Valley, old meadow, very damp- small plots	63 90	176.40
e) Tenaceous stubble; grip and time very good	61 64	150.00
I. — *Berna Tractor* used on military land at Frauenfeld		
a) Good soil	41.66	99.70
b) Light soil 600 metre forrows	33.61	86.95
II. — *Case Tractor:* Good soil, high costs and wages: 17-21 hectares	53.90	92.50
Harrowing 17-24 hectares	—	11.50
III. — *Case Tractor:* 2 repairs every 30 hectares.	34.20	97 20
IV. — *Avery Tractor:* (paraffin-benzine mixture) Large plots grip and time good; 15 hectares	32.50	82.80

V. — NOTES ON MOTOR-CULTIVATION. — The author gives the results of the enquiry made by NICHOLLS amongst 320 American farmers.

---

(1) The question of the transverse ploughing of hill slopes is very important in hilly countries. Good results on moderate slopes were obtained at Basilicata (Italy) with a Melotte trifurrow turn-Wrest plough and Titan tractor. (*Ed.*)

The tractor was stated to be an advantage in 71 % of the farms of an average area of 200 hectares, but not on 70-hectare farms. The tractor lasted 7 years and replaced 2-10 draught animals. The plough recommended the most was a tri-furrow one.

ZIMMERMANN is against a greater speed than 5 km. per hour. A tri-furrow plough should plough 1 hectare of compact soil in 2 $^3/_4$ hours, and mellow land in half that time. If the land is mellow, especially if it is damp, animal haulage is better. Tests made at Grieshof, with an electrical tillage machine, show that to plough 1 hectare, 8-11, 19-22, or 22-25 cm. deep takes respectively a current of 47, 86, or 98 kilowatts; an average according to WERNER of 56 kw.-hrs. If the dynamo is driven on benzine it consumes 20-30 kg. of fuel per hour, nearly as much as a motor-plough. Electricity is more useful than economical.

VI. USE OF CHAIN-TRACK TRACTORS IN FORESTRY. — A communication concerning the RENAULT chaintrack tractor used in experiments made in November, 1920, on the Lower Rhine.

This tractor was used for hauling logs and also for felling. It could haul, over ordinary soil, 3 pine trunks with a total volume of 4-5 cubic metres, although HUFFEL thinks that with the aid of a log-truck it could haul double that amount. After two or three attempts the tractor felled pines which were over 120 years old and 40-45 cm. in diameter. In one hour it felled 10 cubic metres of timber, whilst it takes two practised cutters 10 hours to cut 1 cu. m. The author cannot recommend tractors for drawing stumps, felling deciduous trees or felling trees over 40 cm. in diameter (1).

The author concludes that the utility of the tractor in forestry depend on the following conditions: —

1) Skill of auxiliary personnel.
2) Concentrated and important forestry enterprise.
3) Felling coniferous trees.
4) Animal haulage costing more than 15-25 fr. per cubic metre, and necessitating high wood-cutters wages.

425 - **Substitution of Vegetable Oil for Paraffin as Fuel for Motors and Tractors in the Colonies.** — LEPLAE, E. (Directeur General de l'Agriculture au Ministère des Colonies de Belgique), in *La Nature*, No. 2436, pp. 374-378 + 5 figs. Paris, Dec. 1920.

It is very difficult and costly to transport American or Asiatic petrol into the interior of certain tropical countries. All goods must be carried by native porters, as animals cannot be used because of diseases transmitted by insects such as tsetse flies, etc. But native porters are also expensive and because of these reasons it is advisable to replace them by mechanical transport if a good, cheap, fuel can be found in the country.

---

(1) In experiments made in France, at La Motte Beuvron on June 9, 1920, a 35 H.P. chain-track tractor pulled up stumps 30 cm. in diameter with their roots in 2 minutes, and FLORENT, who reported this, thinks that this time can be cut down by half. He says that the use of explosives and tractor combined should be able to remove the stumps and roots of the biggest size. (See *Journal d'Agriculture pratique*, Year 84, Vol. I, No. 26, p. 489. Paris, June 24, 1920). (*Ed.*)

In October 1919, the author proposed that the Belgian Colonial Ministry should organise a trial of road tractors using palm oil as fuel. This was done in July, 1921, and not in 1920 as was first announced.

But trials directed by an engineer, MATHOT, have already been carried out using palm and cotton oils, in England and Holland. MATHOT carried out complete trials, determined the fuel consumption, and drew up many diagrams. A detailed report will eventually be published when certain experiments that are still taking place have been finished.

The results obtained have opened up vast prospects of the development of central Africa and other colonies. They can be summarised as follows: —

1) Palm oil like cotton oil, when used as sole fuel in semi-Diesel, 2 or 4 cycle engines, gave full satisfaction. The engines ran normally, and the power developed is equal to, if not greater, than that obtained with kerosene. The fuel consumption, at full load, of 15-25 HP. motors tested over 12-15 hour runs, varies between 262-230 grammes per effective HP. hour.

2) Nothing was noted that suggested possible difficulties in using palm oil in semi-Diesel engines. The diagrams are normal. Starting up, without petrol injection, is good, there is no carbonisation, the exhaust gases are clearer than when paraffin is used. Water injection is neither necessary nor desirable. All that is required is to melt the oil by placing it near the exhaust, or running the feed pipe in a coil inside the exhaust.

La Société Belgo-Americaine "La Forminière", (which holds diamond and rubber concessions) possess 3 tractors that run on palm oil and have just ordered 2 more. This oil is also being used at a wireless station in the Belgian Congo.

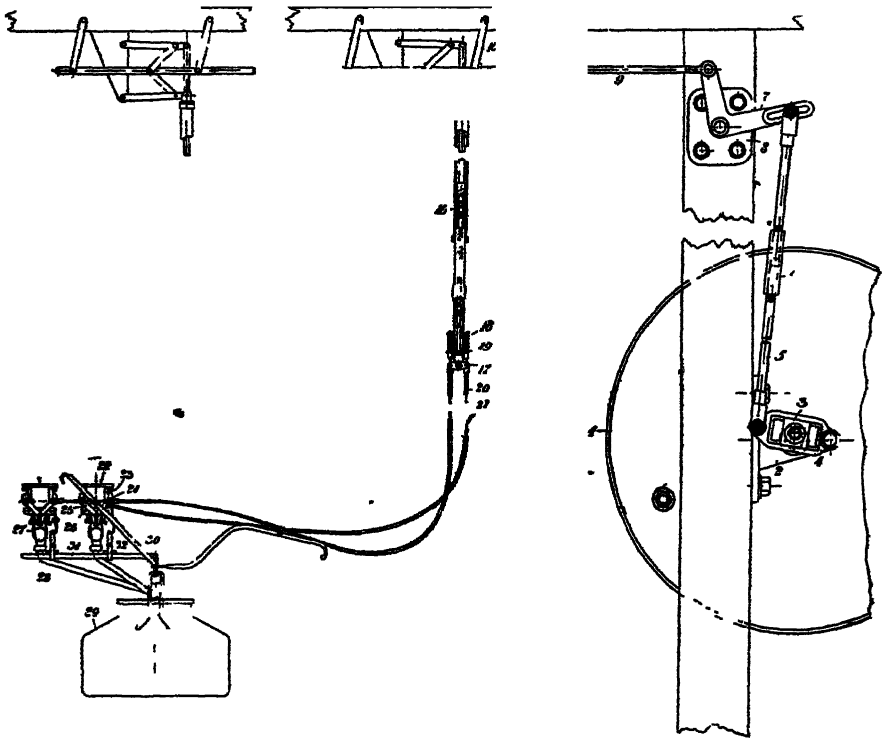
Semi-Diesel engines tested in Belgium in 1919 gave the same good results. A Swedish engine, the DROTT, was tested at Brussels some time ago in the presence of RENKIN, former Minister of the Colonies.

The semi-Diesel engine, is very suitable for propelling boats, locomotives, tractors, and fixed machinery, and is of great practical utility for colonial use. Machines will probably soon be available which in normal times will not cost more than 5-10 centimes for fuel per effective HP. hour.

It is thus evident that vegetable oils, so varied, abundant, and cheap in the tropics, can replace paraffin as a fuel for semi-Diesel engines.

426 - **The Hägg Milking Plant.** — *The Implement and Machinery Review*, Vol. 46, No. 548 p. 1222. London, December 1, 1920.

A description of a Swedish invention which approaches as nearly as possible the ideal standard of mechanical milking. No vacuum, water or air, and consequently no pumps, diaphragms, conduits and suction pipes are used, and the costs of erection and running are therefore on a minimum basis. The HÄGG works silently and gently and produces clean milk, and has a special regulating device which fits automatically to any size of teat. All parts are visible and accessible, and the teat cover is easily removed and another substituted if necessary. No lubricating is required, and an outfit for 50 cows can be driven by a ½ h. p. engine. On the other hand, the apparatus can be driven by hand, and is not beyond the power ordinarily exerted by a boy.



The plant consists of two principal sections, together with a primemover. One section is composed of a pulley with slides and an overhead shafting with couplings; the other comprises the milking device itself with the necessary hand couplings. The pulley 1 and slides 2,3, and 4 are mounted on a pole at one end of the cowshed. By means of a motor or a hand crank. the pulley is set in motion and moves at 70 to 90 revolutions per minute. Slides, and a rod. 5, projecting therefrom, which is provided with a lengthening tube 6, and connected with a bellcrank, trasmit the drive to an angle iron rod 9, which is about 1 inch thick, and is suspended on the links, 10 from and along the ceiling, the rod 9 thus receiving a reciprocating motion. The two small arms 13 transfer the motion from this rod to the overhead couplings 14, 15, each consisting of a rod 14 running within a tube 15, in such a manner that the rod and the tube move in opposite directions. The milking apparatus proper, is suspended under the udder of the cow on two girths supported by the animal, and has four independent teat cups with rubber stalls and celluloid tubes. The whole is set in motion from the overhead shafting by means of the steel spirals 20, 21. The pressure exerted by the teat cups on the teats is adjusted automatically by the levers 17 and the springs 18, and by this arrangement equal pressure in exerted on big or small teats.

The British disposal interests in this machine are placed with Messrs A. D. **Bredengerg** and Co. Monument Buildings, Monument Square. London EC 3.

RURAL ECONOMICS

427 - The Reproduction of the Results of Raising Livestock in the Accounting Status of the Farm. — Kluberger, Prof. Dr., in the *Deutsche Landwirtschaftliche Tierzucht* Year XXIV, No. 16, pp. 15-16. Hanover, April, 1920.

The author has evolved an accurate method for gauging the reproduction and establishment of feeding according to individual requirements (" Fütterung nach Leistung "), of rations necessary for the different groups classed as regards their requirements, as well as the cost of food production (" Fütterkosten ") according to the accounting situation of the farm (" Wirtschaftsetat "). Exact reproduction depends upon the introduction of an empirical estimate (" erfahrungsgemässer Entwurf ") into the accounting. Also it is necessary that the actual conditions of the farm should be reflected in the montlhy live-stock account (" monatlicher Haltungsbericht "), so that at the end of the feeding period (" Fütterungsperiode ") the actual state of the rations, livestock rearing, and cost of food production is reflected in the year-book (" Jahresbericht ") with the monthly accounts for 5-6 months as a basis.

In the empirical estimate, a feeding plan (" Fütterungsplan ") is established based on the monthly books. An illustration of this plan is given below. The data given are taken from the monthly books of a dairy-farm controlled by the author. The market price of straw and hay are included in the Table, as the old assumed price of these fodder crops + land rent no longer exists at present.

Milk Production.

Cost of food production in 6 months.	61 632 *marks*
Milk production 57 060 < 0.60 *marks*.	34 236
deficit . . .	27 396 *marks*

Total cost of livestock raising in 6 months : —

(1) Cost of food production	61 632 *marks*
(2) Interest on 105 000 *marks* a 5 %, 5 % for risk and 1/2 % for depreciation	5 250 »
(3) Cost of manual labour	3 500
Total . . .	70 382 *marks*

$$\text{Cost of production of 1 litre of milk} = \frac{70\ 382}{57\ 060}\ \textit{marks} = \mathbf{1.235}\ \textit{marks}.$$

On this basis of feeding, the agriculturist can easily see the price of rearing a calf from the time it is weaned until full grown. Also he can see the cost of food in the production of a litre of milk, comparatively to the production of the different groups, and is able to give the exact quantity of food necessary per day, and per feeding period. It is obvious that it is necessary to introduce into the general farm account, besides an account for feeding, one for fodder and straw showing the amounts necessary to the farm, and their cost, so as to ascertain what proportion of the whole farm expenses the food represents.

AGRICULTURAL INDUSTRIES

428 - Second Exhibition of Wines from Hybrid Vines at Perpignan, France (1). — LLOBET, J., in *Le Progrès agricole et viticole*, Vol. LXXV, No. 7, pp. 165-167. Montpellier, February 13, 1921.

NOTES MADE ON THE BEST RED WINES EXHIBITED.

No. 5. (Vaucluse) Conderc	No. 3,12.4°	With special flavour, excellent appearance, has a great future
No. 62. Gard	No. 7120,11.5°	Excellent wine, type to be retained perfect table wine, special flavour.
No. 80 (Var).	—	Good ordinary wine, highly coloured.
No. 131 (Var).	rose-coloured	Excellent, very clean taste much special flavour.
No. 167 (Pyr O)	14.4°	Type of very fine Alicante highly coloured, very mellow.
No. 138 (Var)	14.7°.	Type of a cheap wine, good, red table wine.
No. 136 (Var) Siebel 1077 (17° tested)		Excellent "Mistelle" type; from high slopes delicate.
No. 49 (Laudes) Baco 1		Good complete full-bodied, wine coloured type of the French hill-slope wines.
No 51 (Landes) Baco Estellat		Good wine, clean taste, delicate flavour exact type of hill-slope Carignan variety.
No. 25 (Tarn-et Gar) Seibel 4643, 12.80		Ordinary type, very dry, special flavour.
No. 27 (Drôme)		Good, with clean taste
No. 46 (Béziers)		Excellent blending-wine, represents Roussillon type.

---

(1) See *R.*, April 1920, No. 458. (*Ed.*)

No. 89 (Rhône)	Good ordinary wine, colour secondary, delicate. mellow.
No. 108 (Aude) mixture of 7120 and 4643	Excellent ordinary wine, not harsh, pleasant taste, keeps well.
No. 61. (Gard) mixture of Seibel 1, 2044, 4499 and Condere 7120,	Excellent blending wine, Carignan type, dry not harsh.
No. 148. (Gien) Gaillard 194	Rosy type, mellow, agreable.
No. 146 (Alsace) Oberlin 595	Red wine, ordinary type, fruity.
No. 147 (Alsace)	Rosy, dry, excellent.

It can therefore be concluded that, though some hybrids produce mediocre, and very bad wine yet many of them, if carefully chosen, yield an excellent product satisfactory from every point of view, provided due care is given to the making

With the exception of some old Gaillard 157 wines (which were perfect and had a fine Sauterne flavour), Séibel 5213, 4986, 5409, and Castel 1832, the white wines of the year shown at the exhibition were generally defective.

In addition to being too new, and not sufficiently mature for it to be possible to judge of their future value, it appeared that they had suffered from the cold and the journey.

429 - **Action of Oxygen on the Must of Red Grapes.** — I. Piédallu A., Malvezin, Ph and Grandchamp, L., in the *Comptes rendus de l'Académie des Sciences*, Vol. CLXXI, No. 24, pp. 1230-1231. Paris, December 13, 1920. — II. Sannino, S. A., in the *Rivista di Ampelografia*, Year II, No. 1, pp. 10-11. Alba, January, 1, 1921.

I. — Bouffard and Semichon have recorded the action of air upon the colouring matter of rose-coloured musts. (*Revue de Viticulture* Dec., 2, 1899).

During the autumn of 1920, the authors studied the action of pure, finely diffused oxygen upon the musts of red grapes, using for this purpose a cylinder of oxygen compressed under a pressure of 150 atmospheres and a manometer, fitted with a rubber vacuum tube terminating in a Chamberland filter. The experiments were carried out on Aramon, Gamay, and Malbeck musts in casks. As the results obtained were practically the same, the authors only describe one experiment, that made on the Gamay musts.

The fresh must is placed in a deep glass beaker in order that the progress of the reaction may be carefully observed. The oxygen, which is kept at 4 g., passes through the porous walls of the filter and diffuses, in the form of small bubbles, through the must. The latter having the usual colour of thick, red grape must, darkens gradually under the influence of the strong oxidation due to the extremely-finely divided condition of the pure oxygen, and finally becomes quite brown. As the must changes colour, the oenocyanine and the peroxidised tannoid colouring-matters, are precipitated, the must is then filtered, and a golden filtrate slightly tinged with rose, is obtained.

As ZENGHELIS (*Comptes rendus de l'Académie des Sciences*, Vol. CLXX, p 883, 1920) also stated, gases finely divided by passing through a porous membrane, behave as if they were in a nascent condition, their action being thus considerably increased, which explains the rapidity and intensity of the reaction.

CONCLUSION. — The musts of red grapes, which are much used in Champagne and various other parts of France can be made into white, or rose-coloured, wines by the simple expedient of using pure oxygen, which has been very finely divided by diffusion through the porous walls of a Chamberland filter, and without the addition of any chemical decolorant.

II — After referring to the preceding article, Prof. SANNINO adds the following observations: —

The wine-making process studied in this paper has been described, not only by BOUFFARD and SEMICHON, but also previously by MARTINAND of Marseilles. The innovations introduced into the experiment by PIÉDALLU and his collaborators consist in the substitution of compressed oxygen for ordinary air and in the use of a Chamberland filter, instead of a pump, for introducing the gas into the must. The use of oxygen instead of air is not justifiable from the point of view of technique, for ordinary air is a very good decolorant, provided the acid content of the red grapes is not high, and that they contain sufficient oxydase, a fact which is completely disregarded by PIÉDALLU and his collaborators their experiments having been carried out on must from grapes containing little acidity, and hence easily decolorised. As regards economy, air is obviously cheaper than oxygen.

There is however, nothing new in the use of the Chamberland filter. Dr. R. CARPENÈ used it at first in his experiments at Conegliano, but afterwards replaced it by a canvas fire hose attached to a cellar-pump and closed by a plug of wood firmly tied to the end inserted in the must.

The last conclusion, viz., that oxygen can produce colourless or rose coloured musts without the assistance of a chemical decolorant, needs examination and explanation.

It was MARTINAND who proposed the addition of a small quantity of animal charcoal to the must after passing the air through the latter. This was in order to remove the last traces of orange-colour (mixture of yellow and red), or pink, and to prevent the colouring matter that had been rendered insoluble by the air, from being partially redissolved in the alcoholic liquid during fermentation.

Animal charcoal is unnecessary whenever the filtered must assumes a straw-colour after the passage of the oxidising gas; this easily occurs in the case of Isabelle, Gamay, and Aramon musts. If, however, the must' has become brown, filtration will give a golden, orange, on pink must. These colours become less intense during fermentation, but do not entirely disappear, and thus in order obtain light straw-coloured wines, the addition of animal charcoal is necessary.

On the other hand, if the animal charcoal is well purified (such pure charcoal is on the market), it in no wise harms the liquid, odourless must. The troubles arise later, during and after fermentation, at the time when the animal charcoal has lost most of its activity. Exception must naturally be made of the musts of aromatic grapes (muscats), which give wines poor or even deficient, in bouget, if animal charcoal has been used as a decolorant.

430 - Alcohol from the Prickly Pear (*Opuntia vulgaris* and *O. amyclea*). —

PANTANELLI, E., in *Le Stazioni sperimentali agrarie italiane*, Vol. LIII, Part. 12, pp. 451-470, Bibliography of 13 works. Modena, 1912.

The author has undertaken a series of experiments in the manufacture of alcohol from wild plants growing in south Italy (1).

In the present article, he studies the use for this purpose of *Opuntia vulgaris* and *O. amyclea*, two species already cultivated in Sicily, for their edible fruits. The third wild species, *O. Dillenii* is chiefly used for making hedges in the coastal region of East Sicily.

The author passes in review the various attempts to manufacture alcohol from *Opuntia* dating from the middle of last century to the present time, and described his own experiments carried ont in Rome with fruits bought at the market, and hence not fully ripe.

The fruits used in the different experiments consisted of 28 to 32 % of skin, and 72° to 68 % of pulp. The method adopted was as follows: — The fruits were peeled; the pulp was boiled for 20 minutes in half its volume of water; then pressed, and fermented, or crushed and fermented. The skins were treated in the same manner, but separately. The following facts were observed: —

In the natural fermentation of the juice or pulp of the prickly pear, mycoderms, lactic, acetic, and butyric bacteria develop more easily those wild yeasts (*Saccharomyces Opuntiae*); these micro-organisms transform the sugar into substances which are not alcohol, hence impede the use of the cactus for the production of alcohol. If a selected alcohol-yeast is added to this pulp or juice (prepared without heating), the yeasts have to compete with the above-mentioned micro-organisms and cannot give the yield expected. If however, the fruits are pressed, and the juice is sterilised by boiling before the selected yeast is added, the alcohol yield is proportionate to the sugar content of the juice.

Boiling and pressing before fermentation can be dispensed with, if the figs are crushed when cold, and 30 gr. of potassium metabisulphite per quintal is added at the same time as the specially selected yeast is introduced. By this means, a higher yield of alcohol is obtained than by inoculating the boiled pulp with pure yeast for this avoids the destruction of the enzymes present in the ripe fruit which transform the collidal carbohydrates and glucoside into sugar.

In the pulp, and still more in the skins, part of the sugar is found in a glucosidic combination, probably the chromogene of the red colouring matter. During fermentation, this glucoside splits off. There is, in addition, much sugar-producing mucilage as well as traces of starch. The juice must not be treated separately from the pulp. The glucoside and carbohydrates present are used to the fullest extent when the raw pulp has been fermented with metabisulphite and selected yeast.

---

(1) See *R.*, Jan 1909, Nos. 43 and 108. (*Ed.*)

Fruits which are perfectly sound give better results that those attacked by the larvae of *Ceratitis capitata* although they contain less sugar, for they have a higher glucoside content, and the juice although poorer, in soluble substances, is less adapted to the development of lactic bacteria. The alcohol from maggoty fruits also contains more viscid matter, so that the larva-infested portions of the fruits must not be kept for distillation.

With the bisulphite method, at least 9 litres of water-free alcohol are obtained per quintal of fruits, that is, 1 hectare, of especially cultivated *Opuntia* would produce at least 16 hectolitres of absolute alcohol.

There remain in addition: 900 kg. of pressure residuum, good for fuel and containing 64 kg. of oil, 5 kg phosphoric anhydride, and 97 kg. potash and soda; 450 kg. of dry pomace suitable for a compound fertiliser, or stock-feed, for it contains 135 kg. of nitrogenous matter, 6 kg. of phosphoric anhydride, and 13 kg. of potash and soda.

The cost of the prickly pears where they are grown was estimated, in 1919, at 25 lire per 1000, adding the cost of carriage to the factory, which would amount to 2 lire per quintal, the raw material delivered at the factory would, at the present time cost 4050 *lire* per hectare. This would leave a good profit after deducting the expenses entailed in making the alcohol. In addition, the residual pulps and the pomace are of a certain value.

431 – **Changes Taking Place in the Tempering of Wheat.** — TAGUE, E L., (Dept of Chemistry, Kansas Agricultural Experiment station) in *Journal of Agricultural Research*, Vol XX, No 4, pp 271-275, tables 3 Washington D C Nov: 15, 1920.

In milling wheat it has been found advisable to temper or condition the grain before grinding. This process consists in adding a certain amount of water to the wheat, then thoroughly mixing and allowing it to stand for a time. The treatment toughens the bran coat of the kernel, thus making possible a separation of the bran and the flour and increases the desirable milling qualities of the wheat in other ways. The yield of flour is increased and a flour is obtained which permits a better quality bread being made

Three varieties of wheat were used for the experimental work: (1) Kanred. — hard var. with 12.65 % moisture content: (2) Turkey or Kharkof. — hard red var. with 10.86 % ditto. (3). Arizona white wheat, — soft var. with 10.8 % ditto. The only chemical changes considered in this study were changes in hydrogen-ion concentration, total acidity, water soluble phosphorous and titrable nitrogen.

Different periods of time, temperatures and moisture contents were compared as follows: — (1) Time, 24, 48 and 72 hours; (2) temperature, 5°, 20° and 40°C; and (3) moisture content, 15 ½ and 18 %.

When the wheat was tempered at 5°C there was practically no change as compared with the untempered wheat, but as a general rule the yields were slightly higher and the milling qualities were considerably better than those secured from the latter. The length of time appeared to have very little influence on either the physical or chemical composition of the flour.

At 20°C, the hydrogen ion concentration was increased, the total acidity, water soluble phosphorous, and titrable nitrogen were also higher, and there was a distinct advantage over the results at 5°C. The chemical changes were still more pronounced when the grain was tempered at 40° C and the physical changes appeared to be detrimental after 48 hours so far as the milling value of the wheat was concerned. In general the milling qualities of the drier wheats were improved by tempering more than those of the wetter wheats, and the hard wheats more than the soft, and a 15 ½ % moisture appears to be about the best.

432 - **Possible Substitutes for Almond Oil.** (1) — **Apricot and Peach Kernel Oils.** — JURITZ. C. F., (Agricultural Research Chemist.) in *Journal of Industries.* Vol. 3, No. 11, pp. 1052-1057. Pretoria, Nov., 1920.

The apricot and peach kernels, as well as the almonds both bitter and sweet, contain a ferment known as emulsin which consists of two engymes, prunase and amygdalase. This ferment is capable of acting on the glucoside amygdalin producing what is known as the essential oil of bitter almonds, the amygdalin in the process taking up water and forming benzaldehyde and hydrocyanic acid:

Peach kernels yield from 32 to 35 % of fixed oil (*Oleum amygdalae persicae*) which can be substituted without detriment for the almond oil (*Oleum amygdalae*), but owing to the high cost in South Africa its place has been taken mainly by pea nut oil (*Oleum arachis*).

Apricot kernels contain from 40 to 45 % of a similar fixed oil, (*Oleum pruni armeniacae*) which is used as an edible oil in addition to replacing almond oil. The oil may be obtained by crushing and grinding the entire seeds of the apricot, — kernel and shell together, — and the pressing for oil extraction which may be aided by the application of heat or the addition of wàter, or both. An analysis was made by COPENHAGEN W. J. in the laboratory, to ascertain the proportion of oil likely to be yielded by apricot stones, and the physical contents of such oil, and to compare these with recorded analyses of apricot kernel oil from elsewhere.

The following table shows the results obtained: —

Average weight of apricot stone	2.22 gm.
Average weight of kernel	0.47 »
Percentage of kernel in stone	21.35 »

The kernels apart from the shell, were analysed with the following percentage results : —

---

(1) See also *R.* Sept. 1916, No. 1920 (Fixed and Volatile Cherry Oils) — *R.* Feb, 1917, No. 185 (New Process for Extracting Oil from Kernels of Stone Fruit) — *R.* July, 1917, No. 639 (Oil from Plum Stones) (*Ed*).

	In Fresh kernels	In Dried kernels
Moisture	7 06	
Ash	3 10	3 [illegible]4
Proteins (N. × 6 25) .	24 39	20 2[illegible]
Oil .	35 26	37 97

Oil content : — Specific gravity at 15.5°C . 0.9211, saponification value 179, acid value 1.83, refractive index at 40°C, 1.4646, iodine value 112.

The apricot kernel oil, after pressing and allowed to clarify by settling, is almost colourless, but gradually acquires a yellow colour. Its flavour is mild and pleasant. It is however noted that the London firm which claims to have been the first to introduce British-pressed oil of peach or apricot kernels, points out that, although this oil is genuine, and may be legitimately employed, its surreptitious substitution for almond oil should be discountenanced.

The 1914 British Pharmacopoeia lays down the following limits for almond oil : —

Specific gravity 0.915 to 0.920; saponification value 188 to 196, acid value 1.4624 to 1.4640, iodine value 93 to 100. The similarily between this and the apricot oil analysis is evident.

The volatile or essential oils in both cases are derived from their respective sources by processes wholly different from and subsequent to those by which the fixed oils are obtained, namely, by treating with water the cake or marc remaining after expressing the fixed oil, leaving it to macerate for 24 hours or more, and then subjecting the mash to distillation. Bitter almonds yield from 1 to 3 % of this essential oil and the South African apricot kernels, 5 % (*Oleum amygdalae persicae essentiale*). The purification of this oil is effected by redistilling it over ferrous hydroxide. This accounts for the fact that 2 varieties are on the market, one containing and the other freed from hydrocyanic acid, S. A. P. (*sine acido prussico*). That containing the acid is on account of its fairly stable composition, regarded as one of the best-forms in which that powerful drug can be administered.

433 – **Cantaloup feed Oil.** — BAUGHMAN, W. F., BRAUNS, D., and JAMIESON, G S. (Contribution from the Oil Fat and Wax Laboratory, Bureau of Chemistry Department of Agriculture), in the *Journal of the Chemical Society*, Vol XLII, No 11, p. 2398-2401 Easton, Pa, Nov, 1920

Considerable quantities of unmarketable cantaloup (*Cucumis Melo* L.) are allowed to remain on the fields. It the melons are collected and dumped into shallow pits, they soon decompose so completely that the seeds can readily be recovered by raking them from the pits.

A large sample of cantaloup seed was received from the Imperial Valley, Cal An ether extraction showed that these seeds contained about 30.4 % of oil. The seeds were pressed in an expeller, and the chemical and physical characteristics of the oil thus obtained were determined The chemical composition is given in the following table.

Composition of Cantaloup Seed Oil.

		Per cent.
Glycerides of	Myristic acid	0.3
	Palmitic acid	10.2
	Stearic acid	4.5
	Oleic acid	27.2
	Linolic acid	56.6
Unsaponifiable matters		1.1

434 - **Industrial Value of the Waste from Tomato-Canning Factories.** — FACHINI S., in the *Bollettino della Associazione italiana Pro Piante Medicinali, Aromatiche ed altre utili*, Year IV, No. 1, pp. 11-13. Milan, January, 1921.

There are many tomato-canning factories in Italy, especially in Emilia, Campania, Sicily, and Sardinia. The author suggests that the waste products of the industry, which hitherto have only been partly used, should be turned to full account.

The tomato residue, on leaving the factory, contains: 70 % liquid, 22 to 24 % seeds, and 6 to 8 % skins.

The seeds yield, on being pressed, a drying oil with the following characters: —

Density at 15° C	0.9215
Refractive index	1.4745
Saponification value	0.46
Iodine value (Hubl.)	191.6
Iodine value of the liquid fatty acids	140-142
HEHNER index	93.6
REICHERT-MEISSEL index	1.00
Index of neutralisation of fatty acids	199.1
Average molecular weight	291.8
Solid fatty-acid content	12.95
Liquid fatty acid content	87.15
Acetyl value	20.4
BAUDOIN reaction	negative

The results of analyses of tomato-seed cake were as follows: —

	Per cent
Moisture	5.30
Ash	6.50
Crude protein	32.50
Crude fats	12.00
Crude fibre	22.70
Nitrogen-free extracts	21.00

This cake has been found to be an excellent cattle feed, and can be compared with linseed cake.

The oil obtained by pressing well-preserved seeds in the cold, is of a light straw colour, has an agreable taste and constitutes, good edible oil, as is also that yielded by fermented seeds, after the unpleasant acid taste is removed by modern methods of refining. Tomato oil is also used in the soap-making industry. Soap made from tomato oil alone is wanting in consistency, but with the addition of 20 % of suet, palm oil, or coconut oil an excellent laundry soap is obtained.

The crude neutralised oil, can serve as a lubricant, or for lighting; it pays best however to refine it for edible purposes.

From information obtained and laboratory experiments made by the author, it appears that the tomato-canning factories of the Province of Parma alone, furnish annually: —

By the treatment of 800 000 quintals of tomatos, 40 000 quintals of moist waste yielding 9000 quintals of dry seed from which are obtained: —

1620 quintals (18 %) expressed oil.
7200 quintals cake.
2000 quintals (5 %) dry skins.
From the dry seeds, by extraction with solvents, can be obtained:
2070 quintals (23 %) oil.
6750 quintals (75 %) residuum.

Some profit could also be made out of the skins, and the yellow liquid expressed from the damp pomace could possibly be turned to account, as owing to its relatively high content of levulose, citric acid, and fertilising substances, its value is by no means negligible.

435 - **Experiment with the Drying of Vine Fruits.** — Lyon A. V., (Mildura Research Committee), in *Science and Industry*, Vol. 2, No. 10. pp. 625-629. Melbourne, October, 1920.

Experimental work in connection with the drying of Zante currants and sultanas has been in progress for the past 2 seasons. The report here given shows the aim and extent of the investigations carried out by the Mildura Research Committee, in co-operation with the Institute of Science and Industry and the Victorian Department of Agriculture. Two of the principal problems dealt with, have reference to: (1) the estimation of loss in weight in process of drying; and (2) the dipping strength for sultanas, including the relationship of the strength and temperature of dip to the colour of the dried fruit (sultanas).

I. — The sample of fruit for testing was in every case, composed of berries without signs of wilt, as, obviously the density of the juice increases as wilting progresses. The fruit (about 2 cwt. green) was weighed at the green and at the dried stage (unstemmed) for comparison purposes. Results indicated that picking at an early stage (under 13, Baumé reading) is not a paying proposition. In the case of Zante currants, a Baumé reading of 14 shows the minimum stage of ripeness at which they can be profitably harvested.

II. — In field practice it is customary to dip the buckets of fruit in a caustic-soda solution at, or just below, boiling point, or to dip at a ower temperature (190°-195°*F*). At this lower temperature, 15 to 20 % increase in quantity of caustic soda is required to give similar results to those obtained with the boiling dip. In this set of experiments, the following course was adopted with each sample: — A weak solution of caustic soda (1 in 60) was prepared, and strengthened as required by adding more, as calculated to reduce the water relatively by 5 galls, to each 1 lb. of caustic soda. Trials were made at each strength and the maximum and minimum concentrations recorded. All dipping was done at boiling point. The figures obtained were as follows: —

Baumé Reading (as gallons of water to 1 lb. of caustic soda, measure of ripeness). (Commercial 99 %).

Density of dip in degrees Baumé	First cracking	Approaching over cracking
12.1	60	40
13.2	50	35
13.8	45	35
14.15	40	30
14.2	40	30
14.75	30	20

In the operation of dipping, the net result is a concentration in strength and a considerable diminution in volume. An attempt has been made to meet this problem, but this work is at present incomplete.

Although the strength of the dip is only one of the factors controlling the colour of the dried product, generally speaking the quicker the process of drying, the higher and more even will be the colour. Unduly weak dips should therefore be avoided as they lengthen the drying period.

The following recommendations, amongst others, are made by the authors: —

(1) Apply the Baumé test as a measures for ripeness, and delay picking until the juice gives a satisfactory test; (2) Clean out the dip frequently to remake at a suitable strength, and thus avoid variation in concentration as far as possible; (3) Racks should be so placed that they receive a minimum of dust, and dried fruit taken to the packing sheds should be covered, and sufficient rack space provided to secure thin spreading.

436 - **Utilisation of "Rifatto" in the Manufacture of Paper Pulp.** — Di Palma, S., in *Le Stazioni sperimentali agrarie italiane*, Vol. LIV, Pts 10-11, pp. 393-394, Modena, 1920.

In Sicily and Calabria, the term "rifatto" is applied to the ligneous portion of the roots of the liquorice which remains after extraction of juice. A method patented by the author (Municipal Chemical Laboratory, Messina) permits the extraction of a new juice "rifatto," and the entire juice is in this way utilised. After this second extraction, there remains only a small quantity of crude cellulose material in the form of very fine dark red fibres.

"Rifatto" contains about 50 % crude cellulose, which can be utilised in the manufacture of paper pulp, which has an advantage over wood and scraps owing to the high cost connected with the latter to acquire the necessary subsistence.

The experimental tests made with this material in a paper factory at Bergamo have given successful results Considering the large amount of residue which may be collected in Sicily and Calabria the author recommends its use for the manufacture of paper in Sicily.

437 - **The Mat-Industry in Tonkin.** — *Annales de l'Institut Colonial de Bordeaux, Bulletin mensuel*, p. 245. Bordeaux, August, 1920.

The mat industry is a speciality of Tonkin, but with one exception, the factories are in the hands of Chinese. On an average, 3500 metric tons of mats valued at about 2 million francs are exported each year. The native weavers use vertical looms, but French specialists have begun weaving on horizontal ones. It takes 3 or 4 months to learn to use the latter, and the weaving is slower than when vertical looms are employed, but the carpets made are more beautiful, and with a greater variety of shade.

Mat-weaving will always remain a Tonkinese monopoly, for the rushes which form the raw material, cannot be exported on account of their weight. Rushes in their natural condition are sold at 15 *piastres* per 100 kg. in the Ninh-Binh district, and a carpet 3 m × 3.50 m. weighs 25 kg.

438 - **Estimation of Added Water in Milk Analyses** (1). — BOUIN, M, in the *Comptes rendus des séances de la Société de Biologie*, Vol. LXXXIV, No 2, pp 89-91. Paris, January, 15, 1921.

In calculating the amount of added water in watered milk 90 gm. of the fat free extract, an average which is generally agreed to, is taken as. the basis. In many cases, however, the content of fat-free extract is very different from the figure arbitrarily adopted. The author has shown that its normal variations may exceed 20 %, which is enough to prove the uselessness of calculations of added water based on the hypothetical amount of 90 gm. of fat-free extract per litre

Ch. PORCHER (1) is of opinion that the figures relating to the fat-free extract would be more accurate, or more correctly speaking, less variable, if the fat-content of the milk were taken into account. He proposes to substitute the fat-free extract content obtained directly, which he calls the crude fat-free extract (extrait dégraissé brut, E. D. B.) by the fat-free extract of milk that is supposed to have been perfectly skimmed, and which he calls the " rectified fat-free extract " (extract dégraissé rectifié E. D. R.) these two figures being connected by the relation:

$$(E.\ D.\ R.) = \frac{(E.\ D.\ B.) \times 1000}{1000 - \frac{G}{0.92}}$$

G being the fat-content of the milk.

---

(1) See *R.*, May, 1917, No 484; *R.*, Jan, 1920, No. 123. (*Ed.*)

The author states that the lesser variability of E. D R. is only illusory. In fact, the crude fat-free extract is a function of the physiological condition of the cow and varies considerably with the age of the milk He has shown that the fats and fat-free extract which occur in only small quantities in the milk of cows recently come in milk, increase considerably as the end of the lactation period approaches. It can well be understood that, under these conditions, the correlation can but increase the difference between the fat-free extract content of cows recently in milk, and those that have been giving milk for some time.

It would therefore appear to be necessary to find, for the estimation of added water, a less variable constant than the fat-free extract. Cryoscopy is one of the best means of obtaining a physical constant. The following chemical formula suggested by the writer gives results very similar to those obtained by cryoscopic methods: —

$$\text{added water } \% = \frac{85 - (L + 5\,c)}{85} \times 100$$

Here L is the amount of hydrated lactose in 1000 parts of milk. C the crude ash content of 1000 parts of milk, and 85 the average content of the constant $(L + 5\,c)$.

The author applied the various methods of estimating added water to 20 samples of milk, all containing 10 % added water; and found: variations from − 10 to + 11.4 when the crude fat-free extract was taken as a basis; variations from − 13.3 to + 13, when the rectified fat-free extract was used as a basis, and variations of as little as −2.2 and +3.3, when the constant $(L + 5\,C) = 85$ was employed. He therefore states that there should be no further doubt as to the choice of the constant to be adopted in estimating added water in samples of milk.

439 – Comparative Study of Methods of Determining the Fat-Content of Cheese. —

BORELLO, O., in *Le Stazioni sperimentali agrarie italiane*, Vol. LIII, Part 12, pp. 471-493. Modena, 1920.

The estimation of the fat content of cheese is a matter of great practical importance, seeing that many States use the fat content in the Customs classification of cheeses; further, many contracts are based on the classification of cheeses as "nearly fat less," "half-fat," and "fat."

In his experiments, the author has compared the methods of SOXHLET, RÖSE-GOTTLIEB, GERBER, and SCHMID-BONDZINSKI and arrived at the following conclusions: —

The last-named method gives much the highest results.

Two extractions are sufficient to eliminate the fat from the acid solution, the amount remaining in the latter being negligible.

Ethyl ether is the best solvent to use for extraction. The author does not agree with SIEGFELD, who considers the GERBER-method impracticable for a dairy-staff who are unaccustomed to using a chemical-balance.

The experience of 5 years teaching the practical chemistry of milk in in the theoretical and practical cheese-making course given at the " R. Stazione sperimentale" of Lodi, enables him to state that the dairy staff is able to determine the fat content of the cheese according to GERBER's method, even if they cannot give all the details of the operations. An approximative method can always be employed by the chemist, as well as by the technical worker. It gives satisfactory results, especially if butyrometers calibrated for 3 or 2.5 gm. of cheese, with flat tube, are used, each division marking ½ %.

When great accuracy is needed on account of the delicacy of the analysis, or for scientific reasons, the SCHMID-BONDZINSKI method should be used, which gives exact results in a relatively short time. No special apparatus is needed, the ordinary laboratory apparatus being sufficient.

The method becomes excessively simpleed, if a modified a siphon devised by the author is used for decanting off the ether solution, as it is thus possible to regulate, or even stop, the passage of the etherised fatty liquid. By the use of this method, accurate results for any kind of cheese can be obtained.

440 - **The Latest Results of the Enquiry into the Spontaneous Combustion of Hay.** — LAUPPER C., in the *Landwirtschaftliches Jahrbuch der Schweiz, Beilage zu den Mitteilungen des Veterinäramtes und der Abteilung für Landwirtschaft des eidgenössischen Volkswirtschafts-Departments*, Year 34, pp. 1-54, figs. 5, Bibliography of 65 works. Lucerne, 1920.

The author, in treating of this interesting subject, makes use of the copious literature dealing with the matter from the theoretical and experimental standpoints, and in which not only the main question, but also its side issues are discussed. After having spoken of the two previous hypotheses brought forward to explain the spontaneous combustion of hay viz., "chemical" combustion and "biological" combustion, he unites them, and describes the present state of our knowledge of the subject. The rise in temperature of the hay is now-a-days attributed to three different causes, which would seem to produce three phases summarised in SCHENK's figure. In the first phase, the cells of the plants forming the hay are not yet dead, and therefore continue to respire, with the liberation of a considerable amount of heat (interval up to 45°C) and the hay transpires moderately; in the second phase, the fermenting action of the microorganisms, including those that are thermophilous, would appear to come into play, producing a further rise of temperature (interval from 45°C to 70 or 80°C), and the hay transpires profusely; in the third phase, it is supposed that direct chemical oxidation takes place with the assistance of pyrophoric iron, and is accompanied by the liberation of intense heat; then as the hay is already predisposed to overheating, spontaneous combustion ensues (1). After having discussed the arguments as to whether microorganisms, enzymes, or catalytic agents take any part in the process or not, and after comparing this spontaneous combustion with the fermentation of tobacco, the author expresses his opinion that the former cannot be attributed to bacterial action.

---

ON THE DEGREE OF HEAT CAUSING HAY TO CATCH FIRE. — There is one weak side to all the views hitherto put forward viz., the temperature at which hay catches fire was never given. In order to settle this point, a hay combustion experiment was recently carried out at the Swiss Agricultural Experiment Station at Liebefeld (Berne). A large quantity of hay was piled up under a shed, in which was placed a stand holding maxima recording thermometers, that were visible at a distance. Everything was so arranged, that when the temperature of the heap of hay reached 73°*C*., a Wood alloy fused, thus permitting the escape of the carbon dioxide contained in vessel placed in the centre of the hay, and allowing it to penetrate into the latter.

The piling-up of the hay began on Sept. 22, 1916, and the heap was finished on the 25 th. Average moisture of hay 37-38 %. On the morning of the 26 th, the thermometer placed in the lower layers registered 30-32°*C*., in the evening it marked 40°C., whereas the thermometer put in the upper layers registered 50°*C*. On the 27 th, the temperature of the upper part of the heap was 60-65°*C*., that of the centre 51°*C*., and that of the base 47°*C*. From Oct. 2-3, the Wood alloy fused, the vessel containing the CO_2 discharged its contents into the heap, causing the temperature to fall 20°*C*. The hay was already beginning to turn dark, so we may say, that brown hay is produced at about 70°*C*.

The penetration of the CO_2 into the heap of hay only arrested the fermentation momentarily, it continued with even greater intensity after 24 hours, and brought about the third phase, that of hyper-fermentation The thermometer continued to rise and reached 80°*C*.; as for the heap it had already exuded 20.5 % of moisture.

On October 8, the height of the pile had sunk from 2.90 m. to 1.30 m. On October 11, there were 3 carbonisation holes; the hay had turned very brown, it was brittle at many points, and had a very pungent odour, although no smell of actual burning could be detected.

On October 13, at midday, the thermograph of the upper portion of the heap registered 90°*C*., but at 2. 10 p.m, the temperature rose to 388°*C*; the author attributed this last temperature to an error, and thinks that it can be corrected and reduced to 280-300°*C*. At 3 p. m, no ignition, or flames, were observed, and CO_2, was injected.

These experiments show that: — (1) The introduction of CO_2 into a plant mass, that has entered into the most dangerous stage of heating, produces no great or durable cooling, and therefore cannot eliminate the danger of fire; (2) the end of the 1st phase (up to 50°*C*.) was reached in about 2 days; the 2nd phase (50-70°*C*) lasted 6 ½ days; the 3rd phase (70°-90°*C*) 19 days; the 4 th (90°-300°*C*.) had already begun after 2 hours.

Bacteriological analysis shows that the microorganisms probably take no part in the heating of the heap of hay.

Given the difficulty of working on a large scale, the author then discusses the question whether the phenomena of the spontaneous combustion of hay could not be studied in miniature in boxes, or even in glass globes, The author advocated experimenting on a few kg. of hay in boxes, the electric resistance being used to indicate the rise in temperature. It would appear to be very difficult to substitute glass globes for experiments with a heap of hay, for the losses of heat are very great. Nevertheless, after many preliminary attempts, the author succeeded in using a glass globe for the experiment. By adding small quantities of glucose and of ammonium nitrate to the hay, it was possible to supplement the heat that otherwise would have been carried off by the surrounding air and by radiation.

In this way, by using an air oven containing a glass flask, and two thermometers, one outside and one inside the globe, and by regulating the temperature, the author succeeded in imitating on a small scale, within the globe, the thermometric course observed on a large scale in the heap of hay. In fact, by keeping the regulator at 150°*C*, and placing in the globe, hay to which small quantities of glucose and ammonium nitrate had been added, it was seen that, after a certain time of heating at the surrounding temperature (150°*C*), heat was liberated at first slowly, then quickly, and finally very quickly. It was shown by a large number of experiments, that each time the temperature rose to from 280-300°*C*., spontaneous combustion took place in the hay contained in the globe after the breaking of the latter.

The author has obtained in glass globe experiments (by adding glucose and ammonium nitrate) the same graphic thermic curves as those produced by experiments carried out in boxes.

The same experiments prove that the ignition temperature depends upon the amount of sugar and nitrate present, and that if the hay is washed in water, dried, and put into the glass globe, together with the ordinary small quantities of glucose and nitrate, no considerable rise in temperature takes place, which shows, that substances soluble in water are those which chiefly cause spontaneous combustion. It is not enough in order to obtain spontaneous combustion, to add sugars and nitrate to ordinary hay in the globe, it is necessary that the hay should be of the right degree of moisture.

The author afterwards made some experiments in a glass globe, for the purpose of determining the sources of this emission of heat in the hay. He found that: —

(1) The carbonisation of the hydrocarbons begins at 100-110°*C*. and continues with great emission of heat and the liberation of H_2O.

(2) The carbonisation of the cellulose, and other similar compounds, is also of an exothermic nature; part of the chemical heat evolved in spontaneous combustion must be attributed to the exothermic destruction of cellulose carbohydrates, while the rest is due to the sugar carbohydrates being reduced to caramel, or to C, CO_2 and H_2O.

(3) Traces of ammonium nitrate and of ammonia, lower the carbonisation point of the sugar carbohydrates to 70°*C* and even less, which explains the process of formation of brown hay. The starch carbohydrates, after the heat has acted upon them for a long time, are partially transformed into sugars, even by organic acids (oxalic, acetic, formic).

(5) Organic plant acids, even in small quantities, promote to a large

extent the carbonisation of pentoses, pentosans, and other similar compounds.

According to BOEKHOUT and DE VRIES, water plays an important part in the spontaneous combustion of hay, for it transform the substances composing the latter into a condition facilitating oxidation. Further, water brings about the dissociation of the salts of iron and manganese, and consequently causes greater ionisation, and a more intense oxidising catalysis.

In the authors opinion, all these exothermic processes, however, only explain spontaneous combustion, if it is admitted that the balls of compressed hay ("Heufladen"), which are formed in the heap owing to the stratification and compression to which the hay is subjected during the time it is piled up and subsequently, are actual thermic chambers, in which the heat of the exothermic reactions accumulates instead of dispersing. It is as if the living heap possessed an organ of respiration, in which the respiration process of the hay is localised, and where the highest productive capacity and intensity can be reached. In fact, while the heat produced by the initial respiration is used to cause further exothermic reactions and produce fresh heat, the respiratory apparatus of the hay-heap becomes a burning furnace, always situated in the centre of the mass, where the hay is most compressed, and the thermic chamber most enclosed. According to DÜGGELLI, it is only where the hay by its fineness, or great humidity, and in any case, its great compression, is well stratified, that the temperature is very high, and the mass transpires, and becomes bown. At those places where the hay is less compressed, the processes producing heating can only go on to a very limited extent and further, much heat is lost, owing to the circulation of air. The author's experiments on the subject of the rapid thermometric variations in the hay boxes have convinced him that a hay-ball may catch fire at one point, without the fire spreading further. The stalks and fibres which are compressed and adhere to one another owing to the caramelised sugar, play the parts of the wire-gauze in Davy's safety-lamp.

CHEMISTRY OF THE SPONTANEOUS COMBUSTION OF HAY. — The author discusses the problem as to whether it is a question of dry wet distillation, and confirms, by means of his glass-globe experiments, the opinion of TSCHIRCH, who regards the spontaneous combustion of hay as mainly a process of wet distillation, for which the necessary water-vapour is supplied by the transpiring heap of hay. Dry distillation also takes place, but this is confined to the second phase, when the wet distillation is finished.

In order to determine the nature of the substances that play a part in spontaneous combustion, ROCKHOUT and DE VRIES worked up some hay with water, until, there was no further reaction to Fehling's solution, then dried it, and heated it to a high temperature. Under the microscope, the section of washed, heated hay has colourless cell contents, whereas the cellular membrane of the section of ordinary hay undergoing spontaneous combustion is unaltered, but the contents of the cells are black and carbonised. Hence, the substances taking part in spontaneous combustion are chiefly those that are soluble in water, and form a considerable portion of the hay. The author, on comparing the analyses of the same ordinary hay, some of which had been heated, and the rest not, found that, whereas the initial amount of pentosans and nitrogen-free extracts in unheated hay was respectively 22.6 and 30% ; in heated hay the percentage of these substances fell to 8.9 and 10.8 %. It practically follows that the condition of the cell contents and the degree of the maturity of the grass, are the factors determining the spontaneous combustion of hay ; thus the forage and nutritive value of the hay are the measure of its liability to this over-heating, which is also influenced by the agricultural operations before and after mowing.

The author then discusses the different plant constituents which play a part in spontaneous combustion, and gives a detailed account of many of them.

Iron is not found in the aqueous extract of hay ; it appears to remain in the cell-wall. In all probability, however, this element has a threefold function. In the first instance, it would appear to have a catalytic action, like manganese, which depends on the variability of its valency. This catalysis reaches its maximum at 35°*C*., and its limit at 60°*C*. Its second function, which is also of a catalytic nature, consists in the power of greatly increasing the rapidity of carbonisation produced in organic substances by the addition of powdered Fe_2O_3, and especially in carbohydrates, when exposed to heat or a flame. MnO_2, MgO and hay-charcoal when sprinkled ever sugar or other plant substances, also accelerate their combustion. The third function is of a physical character, and the pyrophoric property belongs to the iron and not to the charcoal, as RANKE first supposed. The author bases the statement on the observations he made, in the glass globe, of the thermic course of hay and charcoal, the iron being removed by hydrochloric acid, as compared with that of hay and charcoal from which the iron had not been removed. It is well known that a trace of pyrophoric iron on sugar or sawdust causes it to ignite, white sulphur bursts into flame, and cotton-wool and hay burn with a luminous flame. Manganese, which is of such common occurrence in the plant world, has also a pyrophoric form, though it is less efficient than that of iron, and it is known that many workers regard manganese as a constituent of all enzymes. Magnesium is found in the aqueous extract of hay.

Many experiments have already proved that green plants only accumulate nitrates in darkness. Hay cutting and making, however, take place in day light. The author has reached the conclusion, based on the results of many analyses and observations, that a certain amount of ammonium nitrate (up to 2 %) can actually be formed in a ball in the hay-heap, as a result of purely chemical action.

Among the organic substances playing a part in the chemistry of spontaneous combustion, sugar carbohydrates should first be mentioned ; these occur in large quantities in green plants and hence also in the hay balls, thus some of the carbohydrates become caramelised and impart a viscous, gummy consistency to the hay. Another sugar also forms in these hay balls, in the dark, and especially at night, or as a result of cooling, and the chemico-physiological destruction of the starch. This sugar owing to its solubility in water passes out from the cell contents, thus preventing, at all events to a great extent, the reversal of the reaction.

MIEHE considers enzymes to be agents assisting in bringing about spontaneous combustion. The author finds that in fresh grass the oxydase and reductase are nearly balanced; the latter, however, is less consistent than the former. The oxidase of hay is soluble in water, and contains manganese. Through the action of atmospheric oxygen, it is transformed into a much more active peroxidase (1) that does not appear to be present in grass, and can generate the nitric radicle, Experience shows that in order for the oxydase to be able to induce exothermic reactions, it must be acted upon by ordinary water, as the water which is more or less stably combined with the plant colloids, appears to be insufficient. Since very dry hay is equally liable to spontaneous combustion, the author believes that, in this case, the water necessary for peroxidising the oxydase is obtained in the first instance from intracellular respiration, and in the second, from the *cineresis* of the plant colloids, which consists in the emission of a watery liquid, and occurs with all plant colloids being especially noticeable in dead organisms.

The first phase of the spontaneous combustion of hay is sufficiently explained by normal plant respiration; as regards the 3rd and 4th, when the temperature is over 70°*C*., there is no difficulty in attributing the exothermic processes to purely chemical action.

The question that has been most discussed is, however, the cause of the second phase, between 45°*C* and 70°*C*.; this was regarded by former experimenters as a marvellous point in spontaneous combustion, which perhaps they attributed to a transcendental cause. According to the author, this vexed question can be easily resolved into a problem which finds its explanation in colloidal chemistry, for it is not difficult to suppose, that th oxydases at this temperature are acted upon by the water of cineresis, which brings this second phase into the field of colloidal chemistry.

SUMMARY. — Very dry hay exudes a watery liquid capable of acting upon oxydases, and predisposing them to exothermic activity. This water may be supplied in part by the respiratory process, but most of it is derived from colloidal *cineresis*. Owing to the special physical structure of the heap of hay which permits of actual thermic chambers being formed, the heat liberated during the various exothermie processes accumulates, and increases to such an extent as to determine and explain the most common phenomena of the real chemical processes with their manifestations and consequences. In these processes and manifestations and in the case of temperatures exceeding 100°*C*., it must be admitted that the ammonium nitrate, which has been proved to be present in the hay and especially in the hay-balls, exerts a certain influence.

---

(1) See *R*., June, 1920, No. 628. (*Ed.*)

It is therefore evident that freshly-piled hay should never be compressed, for pressure breaks the stalks, and the water issuing from the latter, in conjunction with other factors, promotes oxidation, which causes the carbonisation of most of the carbohydrates. The critical temperature under normal conditions is between 70 and 80°C. If the forage is badly dried, carbonisation can take place at a much lower temperature; it is therefore necessary to place amidst the hay safety apparatus (patented by Emile RUEGG, Schlossermeister, Zurich,) which should not be removed until the whole mass has cooled.

There are many possible ways in which dangerous oxidation processes may arise in hay, and they are not all due to the temperatures at which normal plant respiration takes place. Therefore, the agriculturist cannot feel quite easy in mind until the carbonisation of his hay has taken place, for even if the hay is very dry, some water be may engendered in the process (1).

441 - Preservation of Canvas Sacks Intended for the Reception of Products Used in Agriculture.

— LAVERGNE, G., in the *Comptes rendus de l'Académie d'Agriculture de France*, Vol. VIII, No. 1, pp. 29-30, Paris, January 5. 1921.

The author, having had occasion to saturate with carbon dioxide large quantities of natural alkali carbonates extracted from Vichy water, spread them, in order to carry out the process, upon screens covered with more or less fine canvas, and found the fabrics were rapidly destroyed by the corrosive action of the damp carbonates, so that it was necessary constantly to renew the canvas. The idea then struck him to silicate the material; this increased the duration of the canvas tenfold, and effected a considerable reduction in expense.

He therefore suggests that the process might be applied for the purpose of preserving the large coarse canvas sacks used for keeping various substances required in agriculture (fertilisers, chemical products, etc.) and which wear out very soon.

The experiment is most easily carried out by diluting one litre of silicate of potash or soda with twenty litres of water, immersing the sack in this mixture until it is well impregnated, then wring it out well in order to recover some of the liquid, which can be used again.

---

(1) The fact that the spontaneous combustion of hay is more common in some countries, such as Switzerland, and less in others, such as Italy, suggests the importance of studying the frequency of spontaneous combustion in different localities and different qualities of hay. (*Ed.*)

PLANT DISEASES

GENERAL INFORMATION

442 – **The Creation of an Institute for the Protection of Agriculture, in Brazil.** — *Ministerio da agricultura Industria e Commercio Regulamento do Instituto Biologico de Defesa Agricola approvado pelo Decreto* N . 14 356, of September 15, 1920, 20 pp. Rio de Janeiro, 1920.

By decree No. 14356 of the President of the United States of Brazil, under date of September 15, 1920, a biological institute for the protection of Agriculture has been created at Rio de Janeiro. The duties devolving upon the said Institute are as follows —

A) The encouragement and promotion of scientific researches and experiments having as their objects a thorough acquaintance with the diseases and pests of cultivated and wild plants, together with the best means for their control

To this end the Institute is required to : —

1) Carry out researches on the action of plant or animal parasites upon plants, and on the pathological changes that ensue.

2) Carry out researches on non parasitic diseases, and on cases of teratology.

3) Study experimentally the immunity or resistance of agricultural plants to their parasites.

4) Study the microbiology of the soil in connection with plant life and growth.

5) Encourage the study of control measures, and experiments in combating diseases, to test insecticidal and fungicidal materials. To answer the questions asked by Associations or private individuals, to take every means of making known the results obtained etc.

6) Establish advanced and special courses of study in matters connected with the objects of the Institute.

7) Inspect and control the importation and exportation of plants, and parts of plants, fruits, seeds, tubers, bulbs, etc.

B) The Agricultural Colleges, Experiment Stations and all similar Institutions and Services under the control of the Ministry of Agriculture, or subsidised by the Federal Government, shall collaborate with the new service.

C) The Biological Institute for the Protection of Agriculture shall include the following services —

1) Service of Plant Pathology

2) Service of Agricultural Entomology.

3) Service of the Selection of Immune or Resistant, Plants.
4) Sanitary Service of Plant Inspection.
5) Laboratory of Soil Microbiology.
6) Demonstration and Experiment Field.

The decree is accompanied by the regulations of the Institute, with detailed information regarding the work of the different services, the staff, and the publications, of the Institute, as well as a complete account of the significance and importance of the new Institution.

443 - **Decree of the Minister of Agriculture Authorising the Importation into Italy of Living Plants, Parts of Plants, Seeds, and other Plant Products.** — *Gazzetta ufficiale del Regno d'Italia*, year 1921, No , 7, pp. 331-332, Rome, March 25, 1921.

With the view of providing the supervision of the importation of living plants, parts of plants, seeds, and other plant products, with the organisation required by the resumption of trade, the Italian Minister of Agriculture has decreed under date of February 21, 1921. —

Art. 1. — The importation from abroad of living plants, parts of plants, seeds, or other plant products, intended for cultivation, or reproduction, must be effected though the Customs Offices of Turin, Milan, Verona, Udine, Venice, Ventimiglia, Genoa, Leghorn, Rome, Naples, Catania, Syracuse, Palermo, Cagliari, Brindisi, and Tarento

Art. 2. — Should packages containing such plants, or portions of plants, be presented at other Customs offices, they are to be refused. They may, however, be dispatched to the nearest of the Customs offices mentioned in Art. 1. if the persons interested intimate to the Customs Authorities their willingness to defray the extra cost of carriage thereby. entailed.

Art. 3. — The cases mentioned in the preceding articles, on arrival at one of the customs offices enumerated in Art. 1., are allowed to be imported after examination by a special Phytopathological Delegate nominated to the local customs Authorities by the Minister of Agriculture, without prejudice to the provisions of Art. 18 of the regulation of March 12, 1916, No. 723 (1).

Art. 4. — If permission is given for the importation of the packages, the necessary precautions prescribed by Arts. 18, 20 and 21 of the regulation of March 12, 1916, No. 723 are taken by the special Delegate, at the expense of the persons interested.

Art. 5. — Citrus trees, or portion of such trees, with the exception of their fruits, no matter whence they have come, which after the examination of the Phytopathological Delegate prove to be free from parasites, are permitted to be imported, but have to undergo a period of quarantine according to Art. 20 of the regulation of March 1916, No 723.

Art. 6. — The provisions of Art. 5 are applicable to fruit trees or portions thereof, with the exception of the fruits, coming from Canada, the United States of America, Chili, the Hawaian Isles, Japan, China, and Australia.

---

(1) This is a regulation relating to the carrying out of the provision of the law, No. 888 under date of June 26, 1913 for the prevention and control of plant diseases. Cf. INTERN. INSTITUT OF AGRIC, *Annuaire international de législation agricole*, Year VI (1916), pp. 875-887. Rome, 1917 (*Ed*)

Art. 7. — The seeds of forage plants may be imported, provided they have been found to be free from any species of *Cuscuta*. This must be ascertained by the Phytopathological Delegate himself, or by an authorised Seed Central Laboratory, utilising a sample taken by the said Delegate. The expenses of carriage and of analysis are charged to the interested persons.

Art. 8. — The importation is suspended of the following plants, or parts of plants· —

(*a*) Cuttings and rooted cuttings of European or American vines coming from France, Spain, the United States and Canada in view of their possible infection with black-rot of the grape (*Guignardia Bidwellii*), without prejudice to the antiphylloxera regulations in force.

(*b*) Plants, bark, or decorticated branches and stems of chestnuts from the United States, as a precaution against American canker (*Endothia parasitica*).

(*c*) Fresh fruits from all the following States . — Canada, United States, Chili, Hawaian Isles, Japan, China, Australia, as a precaution against San José scale (*Aonidiella perniciosa*), *Laspeyresia molesta* and foreign fruit fleas.

(*d*) Citrus fruits from all foreign countries as a precaution against the citrus scale (*Lepidosaphes gloverii*, and the white fly (*Aleyrodes citri*).

(*e*) Potato tubers, the fruits and green parts of Solanaceae (tomatos, egg-fruit plants, capsicums, etc.) from all foreign countries as a precaution against black scab of potato (*Synchytrium endobioticum*, *Phthorimaea operculella*, and the American beetles *Doriphora decemlineata* and *Epitrix cucumeris*.

Art. 9. — The preceding provisions do not apply to importations made at the instance of the Ministry of Agriculture.

Art. 10. — Plant products intended for food and for industrial purposes with the exception of those mentioned in Art. 8., are allowed to pass by all the customs offices, without prejudice to the provisions of Art. 17 of the by-law of March 12, 1916, No 723.

Art 11. — The decrees of the Ministry of Agriculture under date of April 25, 1917 and July 12, 1917, are abrogated (1).

DISEASES DUE TO FUNGI, BACTERIA AND OTHER LOWER PLANTS

444 - **Origin of *Puccinia Pittieriana*, Rust Injurious to Potato in Costa Rica, and to Potato and Tomato in Ecuador.** — ARTHUR, J C, in *Science*, New Series, Vol. VIII, No. 1367, pp. 228-229 Lancaster, Pa, March 11, 1921

In 1920 the author called attention to the threatened introduction into the United States of two rust diseases, *Puccinia Pittieriana* and *P.*

---

(1) See *R*, July, 1917, No. 670, and *R.*, Sept, 1917. No 865. (*Ed*).

Arachidis, the former attacks potatoes and tomatoes and the second the peanut (1). Since then the latter fungus has been found in one field in Florida where all vestige of it was immediately destroyed.

In 1918, *P. Pittieriana* was very abundant in the experiment station grounds at Ambato (Ecuador) and was not only harmful to potatoes but even more so to tomatoes. This was the first report of the rust in South America, having previously been known only on the highlands of Costa Rica on the potato alone. In Ecuador it showed decided preference for North American varieties of tomato.

In January 1920, A. Pachano, (Ambato Station botanist) who makes a special study of the rust question, stated that the parasite was introduced into Ecuador from the United States.

According to later information from the same authority, the disease was not so prevalent during 1919 as it was is 1918, but had the same relative predominance on the tomato, especially on the North American varieties. He also modifies his views regarding its origin. The author considers that the susceptibility of North American varieties has no special significance with reference to the question of native host or habitat. It may safely be assumed that appearance of the potato rust in the gardens of central Ecuador indicates that it may be found on uncultivated native plants in that same region. The Solanum rusts of tropical and semitropical America are numerous, but have been little studied, and those of Ecuador hardly at all.

There is a rust reported from Colombia on *Sarache edulis*, a close relative of Solanum, which much resembles the potato rust except that it has slightly larger spores. This same rust on another species of *Sarache* was found close by *P. Pittieriana* on Mt. Irazú (Costa Rica) by E. W. D. Holway, who notified the author that this plant known as "yerba mora" is common in the gardens there. There is also very similar rust found on the wild *Solanum triquetrum*, ranging southward from central Texas into the adjacent region of Mexico; this form however, has slightly smaller spores than *P. Pittieriana*. Only actual trial can prove if these forms can be transferred from one host to another, and if the size of the spores is in any way dependent upon the host.

A variation in spore-size apparently dependent on the host is found to occur in the cases of other species. The spores from *P. Pittieriana* are remarkably uniform in size. Whether the three forms of Solanaceous rusts here refered to are the same or not, it is fairly safe to assume that *P Pittieriana* originated somewhere between Ecuador and Costa Rica on hosts native to the localities.

445 - Influence of Temperature and Humidity on the Growth of *Pseudomonas Citri* and its Host Plants and on Infection and Development of the Disease (1).—

PELTIER G. L, (Alabama Agricultural Experiment Station, in *Journal of Agricultural Research*, Vol. XX, No 6, pp 447-506, figs 1, tables 21, bibliogr., of 17 works, Washington D. C. Dec, 15, 1920.

Results of experiment tests undertaken at the Plant Physiology Laboratory, University of Illinois, during the winter season 1918-19 and 1919-20, lasting in all for a period of 8 months.

The minimum temperature for growth in culture of *Pseudomonas citri* Hasse the well known cause of the disease of the Rutaceae termed " Citrus Canker, " is about 5°*C*, the optimum between 20° and 30°, the maximum about 35° for a period of 24 hours, and a thermal death point between 49° and 52°.

The influence of humidity on the viability of the organism is very distinct and is closely associated with temperature. At low temperatures, humidity appears to have little or no influence, while at high temperatures and high humidities, it is the limiting factor At medium humidities at all temperatures, the organism is viable for the period of experiment Some factors or factor other than the rapidity of drying must, therefore, be responsible for these results.

The plants to act as host for *Ps. Citri* during the experiments under glass were: *Poncirus trifoliata* (L.) Raf. Rusk citrange (hybrid between *P. trifoliata* and *Citrus sinensis* Osbeck), and *C. mitis* Blanco. The plants were grown from seed in the Crop Physiology greenhouses at Washington D. C A large number of seedlings of *P. trifoliata* were shipped from Auburn (Alabama).

These plants varied distinctly in their reaction to temperature and humidity, especially at low and high temperatures. However, the optimum temperature for all the plants used was between 20° and 30°*C*. Except for a few slight variations, the same temperature relations hold good in the field.

Three conditions are essential for infection: the presence of free moisture on the plant, a suitable temperature, and an actively growing plant.

The life of the organism in culture and outside the host plant is ruled by an entirely different set of conditions from those which control it when it is parasitically active in the host plant. Likewise, the conditions necessary for initial infection of the plant differ.

The period of initial infection must be clearly distinguished from the period of incubation and subsequent development of the disease.

The conditions which determine the most active growth of the host plant are also responsible for the most rapid development of the disease.

The organism is active in the tissues so long as the host cells are active, and when the plant is forced into dormancy the organism becomes inactive and the disease is then quiescent

---

(1) See also *R.* July-Sept 1919, Nos 1038 and 1039 (*Ed.*)

Environmental conditions play an exceedingly important rôle in the susceptibility and resistance of citrus plants to canker.

The results indicate that it will be necessary to study the behaviour of the host plant in its natural surroundings, and its relation to the casual organism before any scientific selection for disease resistance can be made.

446 - **The Influence of Soil Factors in Disease Resistance.** — HOWARD, A. (Imperial Economic Botanist, Pusa, India, in the *Annals of Applied Biology*, vol VII, No. 4, pp. 373-389. figs 5. London, Feb., 1921.

During the last 15 years, opportunities of growing the same crop in India under widely different conditions of soil and climate, and of studying the distribution of the crops have been utilised, and observations on the incidence of disease have been made and of the general conditions which appear to precede serious damage by parasites. An attempt has also been made to ascertain what soil factors are responsible in lowering the natural resistance of a crop to attack. A systematic examination of the root system has been made in every case. The results are here summed up with a view to suggesting the importance of paying much more attention in future investigations of diseases, to the general facts of root development, and to the condition of the absorptive areas of the root system both before the actual advent of the parasite and during the period when the disease is actually established. Up to the present, attention has been paid chiefly to the influence of soil aeration and soil temperature on disease-resistance.

I. *Soil aeration.* — Not only does soil aeration influence the amount of growth, but also the development of the root system and crop resistance to disease, and in some cases actually causes disease. For example, investigations, made with the Java indigo (*Indigofera arrecta* Hochst.) idicated that the wilt disease has no connection with a parasite, but that wilt was produced experimentally in the following ways: — (*a*) By the mutilation of the root system; (*b*) by deep interculture, during the rains, of indigo sown in lines; (*c*) by October and November cultivation of old indigo, dependent for its crude sap on superficial roots which are destroyed by cultivation of the land and encourages wilt. Mulching the surface with straw to preserve moisture and to prevent these roots drying up as the season changes, has the reverse effect; (*d*) by cutting back young rapidly growing August sown plants in October, when the reserve materials in the taproot are insufficient for root regeneration; (*e*) by complete cutting back in cold weather; (*f*) by waterlogging slowly from below during the rains, by closing the drainage opening of lysimeters.

Disease appears to result from damage to the fine roots and nodules under circumstances where root regeneration is difficult or impossible. Wilt generally occurs during the latter half of the rainy season and the agency which may be considered the cause of this effect has been found to be defective soil aeration due to the upward rise of the ground water, combined with the destruction of the porosity of the surface soil by heavy rain which leads to root asphyxiation. Confirmatory evidence that wilt during the rains is due to the destruction of the fine roots and nodules caused by poor soil aeration has been obtained in several directions. Observations have also been made with *Hibiscus cannabinus* L. and sann (*Crotalaria juncea*), where deep rooted varieties are commonly addicted to wilt, but the shallow rooted types are affected to a negligible extent. The surface rooted species like *Hibiscus Sabdariffa* L. thrive, even if the soil occasionally becomes waterlogged.

It is evident from these observations that no parasite appears to be involved in any of the cases mentioned.

In connection with the wilt disease of indigo and of *H cannabinus*, observations were also, made on the conditions which appear to precede the attacks ot two insects *Psylla isitis* Buckt on indigo, and the red cotton bug (*Dysdercus cingulatus*) Fabr. on the latter. It is has been frequently observed at Pusa that applications of fresh undecayed organic manure applied shortly before sowing, as well as oil cake dressings after sowing are always followed by severe attacks of *Psylla*, and in all cases examined root discolouration precedes and accompanies insect attack. A change in the cell sap arising from root damage apparently prepared the way for the red cotton bug on *H. cannabinus*.

The author also studied the rusts of wheat and linseed, and discovered that several of the most rust resistant wheats at Pusa are very shallow rooted in comparison with the deep rooted types liable to disease The same holds good with the linseed, and in this case the shallow rooted types are turgid, white, and exceedingly vigorous and the deep rooted starved and much discoloured. Further observations of the red rot (*Colletotrichum falcatum* Went), of sugar cane leads the author to state that the poor physical texture of black soils appears to render this crop very susceptible to red rot and that soil aeration and healthy root development confer a high degree of immunity on the sugar cane

Experiments conducted in connection with green fly (*Aphides*) on fruit trees showed that there is a definite relation between winter irrigation and green fly, and that the control of greenfly must be sought elsewhere than in the destruction of the insect. The insect can only attack trees in an abnormal condition, and recognition of this fact should be an encouragement to undertake more detailed investigations of the soil, root system and ot the sap of trees affected by green fly.

II. *Soil Temperature.* — Although soil temperature is such an important factor in the distribution of crops in India, both as regards season and areas covered, little attention has previously been paid to this growth factor in considering the occurrence of disease.

One of the difficulties in wheat cultivation in Bihar and the eastern districts of the United Provinces is to establish the crop, and early sowings were in every case destroyed by Termites, while in the later ones the damage was negligible and normal root development and growth took place. The author attributes this to the fall in the soil temperature during the second half of October as Termites were found feeding on a set of seedlings which had been practically destroyed by soil temperature above the maximum for growth. Examination of the root system provided the clue which soon led to the discovery of the cause of the trouble, and the remedy worked out has since been widely adopted on the indigo estates of this tract.

The einkorn (*Triticum monococcum vulgare* Kche.) is well known to be very resistant to the attacks of black rust (*Puccinia graminis* Pers.). In 1907, a plot of this wheat was grown at Pusa when it was found to be immune to all three species of rust which occur in N. E. India. The plants were however still in the vegetative condition at harvest time and were allowed to grow during the hot weather to see if any ears would form. No change of this kind took place, but early in May they were found to be severely attacked by *P. graminis* It should be noted that a prolonged rise of temperature led to a complete loss of disease resistance in a species considered to be immune to this fungus.

Many more examples of disease resistance in other parts of the world must however be examined before it can be definitely stated as to how far immunity depends on morphological root fitness for the environment, and how far it is inherent in the natural resistance of the protoplasm to the invasion of a parasite.

449 - **Fungicidal Dusts for Control of Wheat Smut (*Tilletia Tritici*).** — MACKIE, W. W., and BRIGGS, F. N, in *Science*, new series, Vol. LII, No 1353, pp. 540-541. Lancaster, Pa. Dec., 1920.

Results of using copper sulphate dust in the control of bunt (*Tilletia Tritici*) at Berkeley (California).

The partial success obtained by using flowers of sulphur as a means of prevention in California, and the reported success obtained with copper carbonate (1) in New South Wales encouraged new attempts at dust treatments.

Little Club wheat dusted with spores of *T. Tritici* at the rate of 1 pt. of spores to 750 pts. of seed by weight, and treated according to standard formulas, gave the following results shown in Table.

Sowings were made in rows on the rod-row system on March 8, 1920, and later, which accounts for the somewhat light smut attack. After the grain was threshed, considerable injury to the seed coats was observed permitting maximum copper sulphate injury.

The tests were replicated from 2 to 9 times and the average tabulated.

The results from the various tests demonstrate the effectiveness of copper sulphate dust when mixed with equal parts of calcium carbonated dust, in the control of bunt attack due to seed borne spores. No damage to seed germination occurred. Copper carbonate dust was equally

Copper sulphate and lime dusted separately	»	96.5	0.	0.

effective. These dusts, especially the copper sulphate, adhered closely and completely covered all parts of the seed wheat. The process of shaking the wheat in dusting removed a large portion of the bunt spores. Two ounces of the dusts per bushel are considered ample. Further experimentation is, however, desirable before the dust methods are put into general practice.

451 – ***Cephaleuros mycoidea* and *Pestalozzia Hartigii* Parasites on Tea Plants in Ceylon.** — See No. 393, of this *Review*.

452 – **Plant and Animal Parasites Found on some Medicinal and Essential-Oil Plants in Italy.** — PARISI, R., in the *Rivista di Patologia vegetale*, year XI, Nos. 1-2, pp. 1-16. Pavia, March, 1921.

Prof. F. CAVARA, Director of the Royal Botanic Gardens of Naples, found upon certain medicinal and perfume plants that are largely cultivated in those gardens, several parasites (both plant and animal), which he sent to the author for examination and study.

The plant parasites enumerated are as follows: —

(1) *Physoderma Debeauxii* Bubák, on the leaves of *Scilla maritima*; very injurious to this plant.

(2) *Uromyces Rumicis* (Schum.) Winter, on the leaves of *Rumex Patientia*.

(3) *Phragmidium subcorticium* (Schr.) Wint., on the leaves of *Rosa centifolia*.

(4) *Thielavia basicola* (B. and Br.) Zopf., on young plants of *Atropa Belladonna*, in the propagation green-houses; the fungus had not before been met with on this Solanacea; in 1920, it destroyed 90 % of the young plants in a few days.

(5) *Ramularia variabilis* Fuck., on the leaves of *Digitalis purpurea*; the parasite attacks all varieties of this plant; the least susceptible is

the Sardinian *tomentosa* variety. According to Prof. CAVARA, experiments carried out have shown that the fungus has a considerable influence upon the elaboration of the active principle of the plant.

(6) *Heterosporium gracile* (Wallr) Sacc. on the leaves of *Iris pallida.*

(7) *Macrosporium Papaveris* n. sp., on the young green capsules, of *Papaver somniferum*, var. with white seeds, the author here gives, in Latin, the description of the new micromycete.

(8) *Macr. Cavarae* n. sp., on the leaves, even the cotyledons, of many varieties of *Ricinus communis.* The author describes this species and from what he observed, the plantations of castor plants that had been manured with calcium cyanamide had suffered most from the attacks of this parasite.

(9) *Macr. Solani* Ell. and Mart., on the leaves of *Hyoscyamus albus H. niger,* and *Atropa Bellandonna,* as well as on the leaves and fruits of *Datura Stramonium, D. Metel,* and *D. fastuosa.*

(10) *Pleospora Melissae* (Desm) Parisi on the leaves of *Melissa Officinalis.*

The author mentions the following animal parasites: —

(1) *Heterodera radicicola* Greef, in the root-system of *Althaea officinalis.*

(2) *Chrysomphalus dictyospermi* (Morg.) Leon. on the leaves of some five-year-old specimes of *Cinnamon Camphora.*

(3) *Aulacaspis rosae* (Bché) Chell, on the stems of *Althaea officinalis.*

(4) *Icerya purchasi* Mask, on a single hybrid specimen of " Rose de l'Häy. "

453 -**Wart Disease of Potato (*Synchytrium endobioticum*) also attacks Tomato Plants, in Pennsylvania** (1). — *Weekly News Letter*, Vol. VIII, No. 30, p. 3. Washington, Feb, 23, 1921.

Recent investigations made by the United States Department of Agriculture on the control of the potato wart disease (*Synchytrium endobioticum* (Schilb) Perc, = *Chrysophlyctis endobiotica* Sch lb.), a European trouble found in North America in 1918, disclosed the fact that this disease also attacks tomatoes. Out of 28 varieties of tomatoes planted in the wart-infested gardens of the eastern Pennsylvania, 26 were found to be susceptible to the disease.

It is at present known to be in confined to gardens in a few mining villages in Pennsylvania, West Virginia and Maryland. The disease attacks only the stems and roots of the plant, causing the formation of small warts; it probably does not reduce the yield of fruit.

The importance of the discovery of the susceptibility of tomatoes to potato wart lies in the fact that affected tomato plants will serve to carry the disease over from year to year in the absence of potatoes, and to introduce it into new localities through the transplanting of tomato seedlings grown in infested soil. It is not yet definitely known whether all varieties of tomato are susceptible to wart disease, but it is feared that such may be the case. Other plants belonging to the Solanaceae are suspected of being susceptible to wart and some have already been tested, but with inconclusive results; the tests, will for this reason, be repeated.

454 - **Onion Smut (*Urocystis Cepulae*) in England** (1). — *Ministry of Agriculture and Fisheries*, Leaftet No. 365, pp.-1-6, figs, 2, London, Feb., 1921.

The attacks in England of Onion Smut (*Urocystis Cepulae*) are confined at present to five centres. They occur in strictly localised areas in the following localities: near Northampton, St Neots and Kendal, and in market gardens in two districts in Northumberland.

A description of the disease, method of infection and means of control are here given .

Leeks are, if anything, even more susceptible to smut than onions, so that the cultivation of this crop, and also of shallots, should be confined to soil free from contamination.

The application of a solution of formaldehyde to the drills at the time of sowing, has, however, proved very effective. The Ministry of Agriculture in London is carrying out trials with this substance in the hope of being able to recommend a simple and satisfactory method of treatment.

Onion smut was scheduled in 1920 under the Destructive Insect and Pests Act. Under the Order no person is allowed to sow onion seed in the locality declared by the Ministry to be an " infected place ". Onion plants grown in an infected place may not be removed until the plants have been inspected whilst growing, by an Inspector of the Ministry and certified by him to be free from smut, and have been washed free from soil. Any person in charge of land on which onion smut exists must notify the fact to the Ministry or to an Inspector of the Ministry. If smut is found to exist in any subsequent year, a futher notification of disease must be given. Any person failing to comply with the requirements of this Order is liable to a penalty not exceeding ten pounds (sterling).

455 - **Septoria Iridis, a Spherioidea Injurious to the Iris in Latium.** — COLIZZA, C., in *Le Stazioni sperimentali agrarie italiane*, Vol. LIII, No. 12, pp. 494-504, 2 figs., 1 plate. Modena, 1920.

A fungoid disease of which little is so far known, attacks plants of *Iris florentina* and *I. germanica* in many parts of the Communes of Marino, Grottaferrata, and Albano.

When first infected, the leaves of the diseased plants have on their surface a few, dry, round areas surrounded by a lighther halo. Gradually the number of these spots increases, and the patches tend to extend in a longitudinal direction, and finally assume an elliptical shape. They are often striated, especially when the plants grow in damp localities. The spots increase in number and size, so that finally the leaves wither very rapidly. When the disease is far developed, the lower leaves of the plants wither entirely, and the others are more or less covered with spots. Those on the flower-stalk at once assume an elongated form, and the epidermis and also the cells beneath the spots are completely destroyed by a micro-organism, which, however, is in no way connected with the agent of the disease in question. The plants wither most in the summer; in the spring the disease passes almost unnoticed, as the leaves are young. When the malady has attained an advanced stage, that is to say, as soon as the spots begin to assume an opaque brown colour, small bodies appear which are first yellow and become gradually darker, till they are at length deep yellow. These are the fructification (pycnidia) of a spherioidea considered by the author as the cause of the disease, and which he identifies as *Septoria Iridis* Massal.

---

(1) See *R.* June 1919 No 792. (*Ed.*).

The disease is most commonly met with on plants growing in damp soil and very close together; if thickly planted, the disease also appears, even on dry soils. Under similar conditions, thick clumps of iris are more exposed to the malady than plants growing some distance apart. The greatest injury is to be observed where the soil is rich in organic matter, and where the potash content is insufficient for the requirements of the plants. Artificial infection experiments have proved that the disease spreads without there being any lesions in the epidermis, for the germinating micelium penetrates into the interior of the parenchyma of the leaves and flower-stalks through the openings of the stomata.

As regards the control of the disease, in order to prevent it, or at any rate lessen it as much as possible, the irises must be thinned out every year, and all dry parts or green leaves that show the spots characteristic of the different stages of infection should be removed and burnt, as the spores of the parasite are very long-lived.

It is also advisable to examine the plants from time to time, when first they put forth their leaves, in order that any of the latter which show signs of the disease may at once be removed. Great attention must be paid to the drainage of the beds, and the plants should be liberally supplied with fertilisers containing potash lime and phosphates. The fungicides that give the best results are those consisting of salts of copper and iron, but they are only useful as preventive measures.

456 - ***Botrytis galanthina*** **Mould Injurious to** ***Galanthus*** **spp. in England.** — ARNOT S., in *The Gardener's Chronicle*, Vol. LXIX, No. 1780, figs. 1. London, Feb., 5, 1921.

The author states that after many years experience he has noticed that a mild season, or one with frequent alternations of wet weather and frost, in the time when the fungus (*Botrytis galanthina*) seems to appear most frequently and to be most virulent on the snowdrop plants (*Galanthus* spp.).

The fungus is not difficult to detect if the plants are examined closely. The first appearance consist in a greyish mould around the plant just at the surface of the soil. This mould spreads until the whole, or nearly all the leaves and flowers are covered, should the stem not collapse before that happens. The author does not consider that it is possible to cure each individual plant attacked, as the disease comes from below and the bulbs are badly affected also. He recommends instead, the caraful lifting of the plant and burning it. This should, if possible, be done as soon as the fungus is detected.

It is probable that by spraying the unaffected plants with a fungicide, the spread of the disease might be checked. The author has found that with timely removal of affected bulbs, if supplemented by a dressing of flowers of sulphur on the soil, the disease did not reappear, either in that or the following season on the same groups.

The fungus is not restricted to plants in gardens but has also been observed on those plants which have been naturalised for generations in grass and especially under trees. The author has never seen the disease on *Gal. plicatus*.

In addition to burning the diseased plant it is advised also to burn some of the surface soil round about it and also that which is in contact with the roots and bulb.

457 – **A Bacteriosis of the Ivy Observed in France.** — KILLIAN C., in the *Comptes rendus des séances de la Société de Biologie*, Vol. LXXXIV, No 4, pp. 224-226. Paris, 1921.

LINDAU was the first to describe, in 1904, under the name of "Efeukrebs" (ivy canker), a disease of the ivy which he attributed to bacterial agency, without, however, giving any experimental proof of this assertion. In 1920 ARNAUD added some details to this descriptive study.

In 1916, the author succeeded in isolating the pathogenetic agent and reproducing the disease experimentally, at the Botanical Institute of the University of Strasburg. The micro-organism was isolated from recent lesions, those in the interior of the tissues being selected. Small pieces of pith from the stem were placed in suspension in an infusion of ivy of which some drops had been placed on ivy gelatine. Amongst the colonies thus obtained one species of bacillus was clearly predominant; the author describes its cultural and morphological characters, but does not give its name.

Pure cultures were made during the months of July, August and September under the following conditions:—

(1) Fifty young plants, of erect or climbing habit, were inoculated by punctures made in both adult and young organs, and were kept, for the most part, in a damp atmosphere. The younger portions soon showed the blackening, characteristic of the disease; the adult parts, however, remained completely unaffected; (2) some young control plants punctured with sterilised instruments remained immune; (3) twenty young plants cultivated in pots were successfully inoculated. Thus, cuttings appear to be more susceptible than older plants to the disease.

The bacillus found later in the lesons was compared and identified with that employed in the inoculations.

If the young inoculated plants are kept in an ordinary atmosphere, they show no signs of the disease until after the third week; in a damp greenhouse, however, the black discoloration appears at the end of the first week. The dark patches increase in size rapidly (spreading as much as 1 cm. a day). . They pass from the stem to the petiole, and then to the lamina. The young soft portions of the plant usually succumb when attacked, but the adult parts are more resistant: it often happens that the course of the lesions which have spread rapidly during the first week is afterwards arrested. The greater the age of the stem, the more likelihood is there of its recovery. This is due to the structure of the tissues, as has been proved by the anatomical study of both natural, and artificial lesions In the diseased leaf the centre of infection is easily recognised, it consists of hypertrophied cells that project, raising the epidermis. Around this centre of infection, which is crowded with bacilli, there is a wide zone of dead cells, that pass insensibly into the normal tissues, and are wholly free from micro-organism In the case of young leaves which have been infested from a very early stage, the centre of infection contains no cells, but consists of a large circular cavity full of bacilli, so that there is no spreading of the disease from a central point, such as occurs in the adult portions of the plant.

In the above-mentioned cases, the leaf is probably infected from without, but the disease can also spread internally. When introduced into the stem, the bacilli after having infected the petiole, make their way chiefly along the veins. This is also the usual manner in which they spread through the stem. At first, the parasites are only present in small numbers in the cortex, but they soon multiply there, and destroy the cortical tissues. The walls of the cells being absorbed, leave the way clear for the invasion of the neighbouring cells. Thus, rows of infected cells are formed in the midst of the normal tissues. The latter, when in contact with diseased cells are especially rich in oxalate of calcium and starch. The bacilli collect by preference in elongated cells in the vessels, and generally choose the sieve-tubes, where they develop best. The vascular tissue thus can be infested with bacilli, while the cortex is completely free from them. The bacilli in the stem, following the lines of least resistance, take a longitudinal course, whereas in the leaf, they spread in all directions. On account of the more solid structure of the stem, the progress of the parasites is retarded.

Very frequently, the host gets the upper hand, in which case, wound-callus is formed round the centre of infection, as has been described by LINDAU.

458 - **Disease and Insect Pests of Citrons in Tunis.** — See No. 395 of this *Review*.

459 - ***Fusarium cubense*, Hyphomycete Injurious to Banana in the Philippines.** — LEE, H A , and SERRANO, F. B., in *The Philippine Agricultural Review*, Vol. XIII, No 2, pp 128-129. Manila, 1920.

Plants of the Latundan variety of the banana (*Musa sapientum*) have been observed with banana wilt at Los Banôs and Calamba in Laguna Province, and San Luis, Lemery and Taal in Batangas Province.

According to the investigations made by BRANDES in Porto Rico, the disease is due to the fungus *Fusarium cubense* E. F. SMITH.

The authors have isolated a species of *Fusarium* uniformly from the affected plants in Laguna, which agrees closely with the description of *F. cubense*. The fungus was inoculated with a needle into the pseudostems of healthy banana plants, and the characteristic discolouration was obtained, which is typical of banana wilt. Inoculations with a needle without the fungus have given negative results.

The authors state, that up till now the Latunda variety has in their experience been the only variety susceptible. Other varieties equally desirable also exist which are apparently resistant. Prevention of this disease will therefore be based upon the distribution of resistant varieties to affected localities.

Results from inoculations with *F. cubense* upon abaca plants (*M. textilis*) indicate that the latter is resistant to this disease.

WEEDS AND PARASITIC FLOWERING PLANTS

460 – ***Clathrosorus Campanulae*** **n. gen. and n. sp. of Plasmodiophoraceae, Parasitic on the Weed** ***Campanula rapunculoides*****, in Denmark.** — FERDINANDSEN, C., and WINGE, O., in *Annals of Botany*, Vol. XXXIV, No. 136, pp. 467-469, pl. 1. London, Oct., 1920.

In 1918 in a garden in Sorö, Sealand (Denmark), numerous small swellings, resembling to a certain extent the bacterial tubers of leguminous plants, were observed on the roots of roguing bluebells (*Campanula rapunculoides*).

The authors were able to ascertain that these swellings were due to a parasitic Plasmodiophoraceae sp., evidently a representing a new genus and a new species which has been designated with the name of *Clathrosorus Campanulae*.

Only the cortex is infected.

INJURIOUS INSECTS AND OTHER LOWER ANIMALS

461 – **The Effective Control of the Scale Insect, *Icerya purchasi* by the Coleopteron *Novius cardinalis* in the Oasis of Tripoli.** — LEONE, G., in *L'Agricoltura Coloniale*, year XV, No. 3, pp 140-141. Florence, March, 1921.

For some years past, individuals of *Icerya purchasi* have been observed on various plants in the oasis of Tripoli. In the spring of 1920, there was for a few days a regular invasion of these insects, which threatened to destroy whole plantations of citrus trees in Menscia.

The agriculturists sprayed the plants attacked with different poisonous solutions, but without any satisfactory results.

Thanks to the interest taken in the matter at the Laboratory of General and Agricultural Zoology of the Royal Agricultural College at Portici, the author was able, in July, 1920, to obtain, and transport to Tripoli about 100 individuals of the coccinellid *Novius cardinalis;* these he set free in the citrus plantations infested by the scale insect. Some months later, the coleopteron had already multiplied to a large extent, and the violence of the attack of the scale insects was arrested.

The agriculturists themselves, both colonists and natives, new do all they can to encourage the propagation of *Novius cardinalis;* they take individuals that have hatched out in Tripoli, and set them free in the citrus plantations where *Icerya purchasi* is still to be found.

462 - **Experiments on the Toxic Action of Certain Gases on Insects, Seeds and Fungi.** — NIEFERT, I E., (Insecticide and Fungicide Laboratory. Bureau of Chemistry) and GARRISON, G. L., (Cotton Entomologist, Bureau of Entomology) in *United States Department of Agriculture,* Bulletin No. 893. pp. 1-16. Washington D. C. 1920.

Report of experiments made to test the action of certain toxic gases and to determine the value of these gases for fumigating purposes. The Bureau of Entomology of the United States in co-operation with the Chemical Warfare Service of the United States War Department made experiments on the action of toxic gases upon the body louse(*Pediculus corporis* De G). Nearly 800 fumigations, in which 20 000 insects of about 15 different species were trated, took place. The results obtained as shown in the appended tables, lead to the following conclusions: —

Phosgene ($COCl_2$) is not useful as an insecticide because of its toxicity towards human beings, its high vapour pressure, the difficulty of controlling it, and its comparatively low toxicity toward insects; neither does it possess any value as a fungicide.

Arsine ($As\ H_3$) has no advantage other than the ease of generation and possesses many disadvantages as an insecticide. Its toxicity towards insects is comparatively low, it is injurious to plants, and has no effect on fungi.

Illuminating gas in concentrations up to 3 % and for exposures up to 2 hours is not toxic to insects. Carbon monoxide in concentration up to 3 % and for exposures of 2 hours is also not toxic.

Of the gases tested, cyanogen chloride and chloropicrin give promise of being useful for fumigation purposes. Neither of these, however, can be used in greenhouse fumigation, because of their injurious action on plants. Nevertheless they probably can be used in the fumigation of stored products.

The efficiency of chloropicrin as an insecticide is undoubted and in general, it is more poisonous to stored product insects than hydrocyanic acid. Other advantages which it possesses are ease of detection, and non-inflammability; its disadvantages are its adherent quality, which makes it necessary to air the material for some time after it has been fumigated, its corrosive action on metals, its severe lachrymal effect, and its low volatility. This last objection may be partially overcome by pouring the dose required on paper, thereby increasing the evaporating surface.

As an insecticide, the effect of cyanogen chloride is practically the same as that of hydrocyanic acid. Its disadvantages are its injurious effect on plant life, low boiling point, slighly corrosive action on metal and severe lachrymosal effect; it advantages are that it is active as a fumigant, is easily detected, is not injurious to seeds in doses which a toxic to insects and fungi, and is no more toxic toward human beings than hydrocyanic acid. It is safer to use than the latter because it can be detected in lower concentrations.

More experiments on the fungicidal aspect are necessary to work out in greater detail the methods of its use. Since it is a dry gas and does not injure the seeds, its use would offer a decided advantage over the present method of treatment for fungi, whereby the seeds are moistened, which sometimes causes germination before it is deisred.

463 - **Rice Weevil (Calandra) *Sitophilus oryza* in the United States, especially in Florida.** — Cotton, R. T., in *Journal of Agricultural Research.* Vol. XX, No. 6, pp. 409-422, pl. 1, Bibliogr, of 9 works, Washington D. C. Dec., 15, 1920.

Since the middle of the XVIIIth Century, when it was discovered in Europe, *Sitophilus oryza* has everywhere attracted the attention of scientists which has given rise to extensive literature relative to this weevil It is thought to have originated in India and to have been conveyed to Europe. through commercial transport. At present it is perhaps the most widely distributed of known insects where grain is used. In North America, it is reported from Florida to Alaska, but it is found to be most abundant in the South Atlantic and Gulf States.

The losses at the present time are particularly severe in India, Mexico, South America, and other tropical countries where the weather conditions are such that the weevil can breed unchecked throughout the entire year. Loss is occasioned by both the larvae and adult beetles. The feeding of the larvae is confined chiefly to the seeds of common grains, but the adults feed on a great variety of seeds, fruits, and other food stuffs. In addition to the loss in weight caused by the feeding of the larvae and weevils, infested grain is often rendered unfit for consumption and has a poor germinating capacity.

The author reports the results of observations made in Orlando (Fla.) during the year 1919 and the early part of 1920 on weevils breeding in maize; a description of the various stages in the life history is also given.

The parasites of *S. oryza* are numerous and attack all stages of this insect. A predaceous mite, *Pediculoides ventricosus* Newport, in often found in weevil-infested maize in the Southern States and attacks and kills eggs, larvae and pupae of *S. oryza*. Two hymenopterous parasites, *Cercocephala elegans* Westwood and *Aplastomorpha vandinei* Tucker, are found in large quantities in Florida. In addition to the above mentioned parasites other parasites and predaceous insects are reported not only in the United States, but also in Australia and India. Of the vast number of remedies that have been advocated for the control of this weevil, the most effective agents now known are carbon disulphide and heat.

464 - ***Laspeyresia novimundi* n. sp., Microlepidopteron Injurious to Garden and Field Peas in Wisconsin.** — Heinrich, C., in *The Canadian Entomologist*, Vol. LII, No. 11, pp. 257-258, figs 2. London , 1920.

Morphological description of *Laspeyresia novimundi* as a new species, found in Sturgeon Bay Wisconsin, parasitic on Garden and field peas

(*Pisum sativum* and *P. arvense*). Eight moths have been reared by C. L. FLUKE from larvae feeding in the pods of the foodplants. The adults made their appearance in July

This is the species identified by FERNALD as the European Pea Moth (*L. nigricana* Stephens) and has so figured in Canadian literature. It was first reported in Canada as destructive to peas and under the name *L. nigricana* Steph. has appeared in several American publications. The author is, however, now convinced that this pea moth in Wisconsin is neither *L. nigricana* nor any of the other European *Laspeyresia*.

If *L. novimundi* is not a native species that has passed over to the pea from some wild legume, it has probably been introduced from the Orient. In any case the name *nigricana* does not apply to the insect in question and should be eliminated from the Canadian lists.

465 – ***Cereplastes sinensis*, a Scale Insect Injurious to Citrus Trees and Other Cultivated Plants in Italy and France.** — SILVESTRI, F, in the *Bollettino del Laboratorio zoologia generale e agraria della R. Scuola superiore d'Agricoltura in Portici*, Vol XIV, pp. 3-17, 10 fig, Portici, 1920.

Ceroplastes sinensis Del Guercio was seen for the first time in Liguria, on citrus trees, especially on the "chinotti" (*Citrus sinensis* Risso), and also on some garden plants. The parasite was known in 1900, but was probably introduced into Italy between 1890 and 1896, perhaps with certain ornamental plants of the genus *Muehlenbeckia*. At the present time, it is a common pest in South France. *Ceroplastes sinensis* is probably a native of China.

It 1913, it made its appearance in Naples and Rome, since when it has spread in the southern part of the Province of Naples where it has reached Nocera-Inferiore (Salerno). It has also extended northwards, as for as Maddaloni in the Province of Caserta. The pest has not been reported from Basilicata, Calabria, Sicily, or Sardinia neither has it been found anywhere between Rome and Liguria, or on the Adriatic coast.

The author gives a detailed morphological description of the different stages of the development of the insect, together with an account of its life-history.

The plants on which this scale-insect thrives best are, according to the author's observations: — *Schinus molle, Muehlenbeckia platyclados, Veronica speciosa, V. salicifolia, Chrysanthemum frutescens, Chrys. grandiflorum ;* after which come citrus-trees (the "chinotto," mandarin, orange etc.), *Euonymus japonicus, Spiraea chamaedryfolia, Philadelphus coronarius, Aster formosissimus, Dahlia variabilis*, and *Salvia splendens*. Some authors also mention as host-plants of this parasite, *Gardenia florida, Amaranthus* sp., rose-trees, pear, and apple-trees, but until the contrary has been proved, the presence of *Cer. sinensis* on these last and especially the pear and apple, must be regarded as accidental, and confined perhaps to the early stage of the insect, at which period it is even found on a number of herbaceous plants growing in the vicinity of the infected trees, such as French beans, maize, etc.

It is necessary to bear this fact in mind, so as not to introduce into a district free from this scale-insect, any kitchen-garden or ornamental plants, or shrubs, trees, or portions of the same, that have been grown in an infected place. This is especially to be avoided between July and November.

It is known that the hymenopteron *Scutellista cyanea* is an egg-parasite of *Cer. sinensis*, but it seems to do little damage to its host. Certain coleoptera (*Chilocorus* and *Exochomus*) also attack the newly-hatched larvae, or the small fixed larval individuals, but in such small proportions, that it cannot be said they render a valuable service to agriculture. At Portici some large male larvae were seen to be attacked by a hymenopteron (*Aphicus*).

In its native country, the scale-insect must undoubtedly have one or more natural enemies that control it efficaciously. These should be discovered, studied, and introduced into the infected districts of Europe

466 - ***Tylenchus* sp. Nematode Injurious to the Banana in North Queensland.** — ILLINGWORTH, J. F., in *Queensland Agricultural Journal*, Vol XIV, Pt. 7, pp 297-301, pl. 2. Brisbane, Dec, 1920.

In 1917 a survey was made of the affected banana gardens in the Freshwater area in Cairns and the plants were found to be in a seriously damaged condition All of the lower leaves were either dead or dying, the others were lacking in their usual healthy green colour, the bunches were very much dwarfed.

Digging the plants proved that most of the rootlets were dead or rotted, and the larger roots showed decay in patches particularly at the points where the rootlets had disappeared. The surface of the corm, too, showed brown diseased areas.

Some of the diseased roots were selected and thin cross sections made, cutting through the darkened areas where the roots had rotted off. Examination of these sections under the microscope revealed myriads of Nematode worms (*Tylenchus* sp.) in all phases of development, especially at the point of contact of disease and sound tissue. It is not surprising that these organisms have not been discovered before since there is no apparent enlargement of roots, and after the material is preserved it is difficult to locate the pests and it is mainly the activity of their movements in the tissue of the host that makes them visible.

As regards control measures, recent investigations made by A. H. BENSON has brought into evidence the efficacy of dipping banana plants, prior to planting in a 1 in 1000 solution of corrosive sublimate for 2 hours; no injury was done, even when allowed to remain in the solution longer than the prescribed time. The suckers thus treated were planted at depths of 12, 18 and 24 in. All developed very satisfactorily, those planted at 12 cm, deep made the earliest start; eventually producing the best plants as well as developing the most suckers. So far, no nematodes have been discovered on the roots of any of the treated plants irrespective of the depth of planting

It is also recommended to make experimental trials with arsenic acid.

This should be due by dusting the corms and the holes where they are to be planted, also by mixing the poison with the soil in infested fields, before planting out the sets. Lime, too, may have some value, and should be used at the time of planting.

467 - ***Laspeyresia conicolana*** **a Microlepidopteron Injurious to** ***Pinus Laricio*** **var.** ***tenuifolia*** **in France.** — NÈGRE, M., and PICARD, F., in the *Bulletin de la Société entomologique de France*, No 1 pp 10-12, 1 fig. Paris, 1921.

In the forest of Saint-Guilhem-le-Désert, there has been discovered on *Pinus Laricio* var *tenuifolia*, a tortricide, *Laspeyresia* (*Grapholitha*) *conicolana* Heyl., which is probably new to France; it has hitherto only been found in Holland and Lower Austria, where it attacks the cones of *Pinus sylvestris*.

It 1914, observers noticed for the first time that this insect destroyed many of the seeds of *P. Laricio*, var *tenuifolia*. In 1920, the investigations were resumed, and it was found that the pest was still continuing its destructive work and that most of the pine seeds had been devoured by it.

When reared, the moths appeared in April, or at the beginning of May, that is to say, earlier than in Central Europe, where they emerge from the chrysalis in May or June.

L. conicolana has only one generation. The moths deposit their eggs in spring, the caterpillars hatch out in the summer, hibernate in the larval condition, and do not pupate until the following spring; a fortnight after pupation, the moths emerge Some larvae were found at the beginning of April, as well as many chrysalids. The caterpillars are whitish, their heads being dark brown and not yellowish green with black heads as has been stated. Perhaps they vary in colour, according to their age. The larvae make their way along the axis of the cone, and pupate among the scales. The moths reach the exterior through the free end of the scale, carrying with them the pupal integument which remains attached by the point to the substratum. The cone appears deformed, and much bent. This is due, as careful examination proved, to the insect remaining in the axis during development, and is not, as CALAS supposed, a distictive character of *P. Laricio* var. *tenuifolia*.

In addition to *L. conicolana*, the larvae of a cecidomyid were also found infesting the cones of *P. Laricio*, which they injured to a great extent. No adult forms of this insect have so far been found. They attack the cone soon after its formation, probably in June-July. The puncture causes much resin to exude, which renders the cone turgid, displaces the scales, and makes it deformed. The cone ceases growing, and dries up during the first autumn, or the following spring. In 1914 more than half the young cones of *P. Laricio* var. *tenuifolia* in the forest of Saint-Guilhelm-le-Désert were of the characteristic shape due to the attack of the dipteron, which also injures the fruits of *P. silvestris*: it is very rarely found elsewhere in the locality in question.

GENERAL INFORMATION

468 - **Researches on the Bacteria of Certain Kitchen Garden Plants.** — LA CAMERA, P. (R. Istituto Batteriologico della R Scuola Superiore d'Agricoltura in Portici), in *the Bollettino Veterinario Italiano*, Year XVIII, No. 146, pp. 446-447. Turin, February-March, 1921.

The author has examined, from a hygienic point of view, certain kitchen-garden plants which are usually eaten raw, viz., common fennel (*Anethum phoeniculum*), celery (*Apium graveolens*) various kinds of Roman lettuce (*Lactuca sativa*), and endive (*Cichorium Endivia*). The specimens studied were taken, all aseptic precautions being observed, from kitchen-gardens in the vicinity of Naples which had been manured with dirty water, sewerage water, night soil, road-sweepings, and dung.

The author noticed the presence, in every case of 4 species of micro-organisms of which 3 were characteristic: — 1) A bacillus that quickly liquefies gelatin and produces a foetid gas, and which the author proposes to name *B fluidificans foetidus*, or *B. f. putridus*; 2) and 3) two entirely anaerobic non-liquefying bacilli; one of these produces a substance causing fluorescence in the gelatin and imparting an emerald green colour to broth; it also gives off an unpleasant odour. The author is of opinion that the two last-named micro-organisms are forms of *B. fluorescens putridus* The fourth bacillus is a small, innocuous form that is always present in the air, soil, and water.

These 4 kinds of bacteria do no harm to the organism, and appear to reduce the organic matter composing the manures, that is to say, they act as purifiers of the soil; they are saprophytes, and are serious rivals of certain parasitic micro organisms, such as the organisms of anthrax and typhus.

469 – **The Influence of Diet on the Antiscorbutic Potency of Milk.** — I. HART, E. B., STEENBOCK, H., and ELLIS, N. R. (Dept. of Agricultural Chemistry, University of Wisconsin Madison), in *The Journal of Biological Chemistry*, Vol. XLII, No. 3, pp. 383-396, pl. 1,, figs. 14. Baltimore, M. D., July 1920. — II HESS, A. F. UNGER L, and SUPPLÉE, G. C. (Bureau of Laboratories, Dept of Health, N. Y), *Ibid.*, Vol XLV, No. 1, pp 229-235, figs. 2, table 1, bibliogr of 5 works. December, 1920

I — For the purpose of studying restricted ration problems, a herd of 18 cows, all of which were kept yearly on air-dried roughages and grains was maintained. No fresh green vegetable tissue was even fed to the herd.

Results showed that the milk thereby obtained was distinctly inferior in its content of antiscorbutic vitamine to the milk derived from cows receiving a part of their ration as summer pasture, which consisted of fresh green material. The summer pasture milk was derived from cows which, during part of the day grazed on timothy, blue grass and clover land. When used with the basal ration for guinea pigs (a mixture of heated alfalfa hay, finely ground, rolled oats and common salt), 15cc. daily of summer pasture milk per individual afforted protection against scurvy for 20 weeks. However, 50cc. was a safer limit for complete protection. At least 75cc of dry feed milk daily was required per individual for complete protection against scurvy

The winter feeding of dairy cows was in these experiments limited to a ration consisting of grains, mixed hay, a small amount of silage, (10 lb. per day)., and the hybrid sugar mangel (*Beta vulgaris* var.). Silage or sugar mangel milk was classed with dry feed milk and not of the order of green summer pasture milk in respect to its antiscorbutic vitamine There is a certain amount contained therein but this vitamine is too low a content for protection of a guinea pig against scurvy.

II. — The investigations undertaken by HESS, UNGER and SUPPLEE differ from the above mentioned experiments mainly in the delimitation and duration of the feeding periods, and in the inclusion of a chemical examination of the 2 varieties of milk. The cows had been stall-fed throughout the winter on a normal winter ration of ensilage, hay, and concentrates. From the end of April onwards, the diet was selected to provide a food which was ample in all respects excepting in its quota of antiscorbutic vitamine. After 3 weeks of this antiscorbutic free ration. — (25 lb. concentrate mixture consisting of 1 pt. bone meal, 2 pts. oil meal (flaxseed extracted by pressure), 2 pts hominy, 2 pts gluten meal, and 2 pts of bran, 8 lb kiln-dried beet pulp: 4 qts. molasses and 12 lb. of straw), the general health of the cow had not been maintained, and there was an average decrease in milk flow of 5 lb. per day.

The cows were then placed on fresh grass pasture for 3 weeks. The physical condition of 3 cows showed marked improvement but the others did not respond so quickly to the change in fodder. The production of milk did not increase materially. The milk was dried before using for feeding tests and Guinea pigs were then fed the equivalent of 80cc. per head daily in addition to oats and bran.

All the guinea pigs fed with dry fodder milk developed scurvy within 21 days and died within 56 days. On the other hand, animals which had received pasture milk lived for 120 days, and are still alive, two only showing mild signs of scurvy The contrast is striking and definitely illustrates the marked difference in antiscorbutic content of the 2 varieties of milk

A study of the analyses tables shows that the fat, protein and sugar percentages were very similar, but that there were certain well defined differences in the composition of ash of the 2 milks, the percentages of calcium and of phosphorous were significantly higher in the pasture milk and its citric acid content was over 50 % greater. There was however, less sulphur in this milk in spite of its somewhat higher protein content.

The authors consider that from this chemical examination, there is an evident danger of setting up rigid standards for milk constituents, and advocate the necessity of prefacing such results with full data as to the diet of the lactating animal

470 - **The Bacteriophagus Microbe. Immunity Agent in Plague.** — See *Review* April 1921, No 399

471 - **Annual Report of the Agricultural Experiment Station of the University of Wisconsin, 1918-1919.** — RUSSELL, H. L., and MORRISON, F. B., in *Bulletin* 319 *Agricultural Experiment Station, University of Wisconsin*, pp. 1-76, figs 29 Madison, Wisc., 1920.

Report of the experimental work conducted at the Station 1918-1919 ; brief resumés of publications issued by the station and financial statement for the year ending June 30, 1919.

Results of the more important experiments may be summarised as follows.

PRINCIPAL CROPS (pp. 3-26). — *Hemp*. — In the United States, Wisconsin occupies the leading position as regards the production of hemp, and in 1918-19 grew 4750 acres, *i. e* nearly one-third of the total acreage of the United States, and the quality of equally high value to the best quality hemp grown elsewhere.

According to the results obtained by A H. WRIGHT, hemp may be grown on various types of soil in divers localities, especially in the north

WRIGHT also conducted experiments with a view to improving the sorghum crop and methods for sorghum syrup manufacture. Experiments made in collaboration with farmers showed that varieties coming from the south-west of Wisconsin ripen very late owing to prevailing climatic condition.

NEW FACTORS IN THE PRODUCTION OF SILAGE (pp. 41-42). — E. G. HASTINGS (Agricultural Bacteriologist) indicates that the first organism which appears in considerable numbers in silage is one of the *coli* This produces a very considerable amount of carbon dioxide, small amounts of acids and from 0.6 to 0 7 % of alcohol.

The following experiment indicates that the formation of acid is due to the presence of bacteria : — Peas were grown in large test tubes, and after maximum growth had been attained were transferred to smaller containers which were immediately sealed. In these, none showed any signs of acid production

INHERITANCE OF MILK AND MEAT PRODUCTION IN CATTLE (pp. 53-54). — Crosses were made by L. J COLE between the two races Jersey cows and Angus bulls and results showed that the 1st generation cross-breds were all black polled like the Angus but in most other respect showed individual variation especially as regards milk production and meat production In the 2nd generation there was distinct variation in the matter of colour and horns. Some of the crossbreds, particularly the males possessed horney scurs, loosely attached to the skin.

BARLEY VERSUS OATS FOR WORK HORSES. (pp. 68-69). — As the result of an experiment with 10 teams of work horses made by MORRISON, BOHSTEDT and FULLER it may be concluded that crushed barley is about 10 % superior to crushed oats for horse feeding.

BARLEY VERSUS MAIZE FOR MILCH COWS. (p. 68). — Experiments conducted by MORRISON, HUMPHREY and HULCE.

Experiment I. — Two lots each of 6 cows were fed by the reversal method for 2 periods of 6 weeks each. When fed with a 60 % concentrate mixture (in addition to the ordinary roughage) of ground barley, the average daily yield of milk was 25.1 lb., and of butterfat 0.92 lb., and with others fed with ground maize instead of barley, the average daily milk yield was 25.6 lb., and of butterfat 0.94 lb, there was, however, a loss in weight with cows on the maize feed.

Experiment II. — Two lots each of 5 cows were fed by the reversal method for 3 periods of 5 weeks each When fed in addition to pasture with 5.6 lb., of a mixture consisting of 60 lb., maize, 30 lb., wheat bran, and 10 lb., cotton seed meal, the average daily yield of milk was 26.3 lb., and of butterfat 0.94 lb. When the same amount of ground barley was substituted for ground maize, the average daily yield of milk was 26.9 lb., and of butterfat 0.96 lb. The cows appeared to show a slight gain in weight on the maize ration and a loss on the barley ration.

FATTENING STEERS WITHOUT FEEDING MAIZE GRAIN. (pp 71-72) — Two lots each of 10 steers were fed by FULLER and MORRISON · Lot I fed on a an average daily ration, per head of: 12.5 lb shelled maize + 2.8 lb., cotton seed meal + 32.6 lb., maize silage, + 2.2 lb., mixed hay; Lot II on 3.6 lb., cottonseed meal + 56.6 lb., maize silage + 2.6 lb., mixed hay.

The gain in weight in both cases was more or less identical, Lot I showed, however, a better finish and shrank less in shipment and secured a somewhat higher price than those in Lot II.

BARLEY, SKIN MILK AND WHEY FOR PIGS (pp. 67-70-71). — Experiments conducted by MORRISON and BOHSTEDT: —

As a result of comparative tests with self-fed ground barley + tankage and self-fed shelled maize + tankage it was demonstrated that barley fed pigs required 15 % more grain but only about $^{3}/_{4}$ as much tankage as the maize fed pig

In the tests to ascertain the comparative value of skim milk and whey. made with pigs which averaged 137 lb., in weight, those fed on self-fed ground barley and tankage (given separately *ad libitum*) showed an average daily gain in weight per head of 1.64 lb., but the skim milk fed pigs gained 1.89 lb.

The tankage pigs required 450 lb., of barley and 23 lb, of tankage per 100 lb. gain. The skim milk pigs required only 406 lb., of barley and 340 lb, skim milk per 100 lb., gain.

MANUFACTURE OF CHEDDAR CHEESE AND CONDENSED MILK (pp.43-44). — With a view to regulating the flavour of cheddar cheese manufactured in the pasteurising process, experiments have been made by HASTINGS and SAMMIS by adding to pasteurised milk a lactic acid starter, and also a special starter made from digested milk which had been inoculated with material from certain natural foci of infection. Results gave cheeses with a marked improvement in flavour compared with control cheeses made from pasteurised milk by the regular process.

It has been demonstrated by SOMMER that the amount of acidity of fresh milk, has nothing to do with coagulation when the titration method is adopted, and the titration method employed in the condensories cannot therefore be regarded as a direct means of determining the suitability of milk for condensing It appears that milk with too much soluble lime will have a low coagulation point, but this can be corrected by the addition of either citrates or phosphates, which render the calcium less soluble.

CROPS AND CULTIVATION

472 – **Effect of Late Spring Frost upon Forest Vegetation in the Wasatch Mountains of Utah, U. S.** — KORSTIAN, C. F., in *Ecology*, Vol. II, No. 1, pp. 47-52, figs. 1, bibliogr. of 6 works Brooklyn, N. Y, Jan. 1921.

There was on exceptionally warm spell of weather in May 1920, and it was in fact the warmest May for 18 years. But at the end of the mouth (30th and 31st) the weather was unusually cold and considerable damage was caused to the native vegetation in the forests (all growth was on account of the season, about 3 weeks earlier than normal).

At the Cottonwood Nursery, located 25 miles south-east of Salt Lake City, at an elevation of 7400 ft., snow fell to a depth of 5 in , and during the night a minimum temperature of 15° F was reached.

A careful examination was made of all stock in the nursery, and of the native vegetation on the adjacent mountains; in order to obtain an idea as to the extent of damage caused by the frosts and the effect on each species individually

(1) *Picea Engelmanni.* — Trees 2 to 4 years old were seriously injured; the buds which had just opened had practically all the terminals, and many of the laterals of the current seasons growth killed. A few trees were killed entirely, others had a portion of last season's growth destroyed.

(2) *Picea Parryana.* — Approximately 10 % of the taller terminals were killed (a covering of snow protected the majority).

(3) *Pseudotsuga taxifolia.* — Seriously injured: stock rendered practically worthless.

(4) *Picea excelsa.* — Injured only to a slight extent.

(5) *Pinus ponderosa, P. contorta* and *P. monticola* — exceptionally resistant.

(6) *Abies lasiocarpa* and *A. concolor.* — Injured to a greater extent than the spruces.

In the nursery, it appears then that the *Abies* suffered most, followed by *Picea* and last by *Pinus*, evidently the most resistant.

In the forest, the greatest danger lay in the southern, south-western, south-eastern exposures as vegetative activity begins later; and for similar reasons the greatest amount of injury was observed at elevations of from 7000 to 8000 ft.

Acer Negundo, Alnus glutinosa, Sambucus sp., *Fraxinus excelsior, Acer campestre, Quercus* sp. (Gambel oak) were senously attacked by frost, and in many cases the previons seasons growth was killed.

Symphoricarpus oreophilus, Ceanothus velutinous, Ribes viscosissimum and *Prunus melanocarpa* were only partially frozen, and the damage was limited to current growth.

Naturally the well developed leaves fell to the ground, and the trees presented a winter aspect. At the end of June, however, a number of dormant buds on the growth of the previous year, which had not been killed off by frost, developed newly formed adventitious buds and new leaves.

The full vigour of the tree appeared to be concentrated into the relatively few stoots and new leaves, producing exceptionally large specimens ; in some cases measuring 8 ½ × 10 inches.

The contrast between normal and affected leaves was especially noticeable in the case of *Populus tremuloides*.

473 – **Irrigation Experiments with Sewage Water in Florida. U. S.** — Stalbner, F. E., in *Engineering News Record*, Vol. 85, No. 18, pp. 846-849, figs. 3. New York, Aug., 28, 1920.

The author gives a description of an irrigation system with sewage water, constructed by the Florida Agronomic Station in collaboration with the United States Department of Agriculture. It is constituted thus : — a septic reservoir — a layer of broken up stones forming a filter — an overflow — a condenser drain — a pump — 8 discharge plugs, acting automatically — a distribution canal system. According to when the lower plug is open or closed, the liquid which comes out of the filter passes directly over the field or rises to the upper part of the overflow and passes, across the lateral pipes, into the reservoir. The discharge into the lateral pipes is regulated by the automatic floating valves.

474 – **The Reversion of Superphosphate.** — Neumann, B., and Kleylein, K. (Mitteilungen aus dem Institut für chemische Technologie der Technischen Hochschule Breslau), in the *Zeitschrift für angewandte Chemie*, Year 34, No. 18, pp. 77-80, and No. 19, pp. 84-86, 16 Tables. Leipzig, March, 1921.

The reversion to an insoluble state of the phosphoric anhydride of water soluble superphosphates is a chemical process facilitated by 3 conditions:— (1) keeping the superphosphate for a long time in large heaps (especially if there is a deficiency of hydroscopic water and if the temperature is high); (2) the richness of the original phosphorites in aluminium compounds and, more especially, in iron, (3) in complete treatment with sulphuric acid in the lead chambers

The author summarise the previous work of Messrs. ERLENMEYER, OTTO, JOULIE, STOKLASA, SMETHAN, HERBST and SCHUCHT.

The objects of the authors' recent experiments were to determine to what extent, and in what manner, metallic sesquioxides effect the reversion of the phosphoric anhydride, and whether this could be prevented by any change in the method of manufacture.

Superphosphate contains tricalcium phosphate (which has escaped disintegration), monocalcium, and possibly even bicalium phosphates, but above all, free sulphuric acid, which acts in two different ways, both hindering and promoting retrogradation; in addition all these substances, as well as the iron and aluminium compounds, bring about reactions the products of which tend to react upon one another. For these reasons, the authors began by isolating the different substances that react when pure; they studied experimentally the phases of reaction, counter-reaction, and chemical equilibrium, and then gradually passed to the consideration of industrial superphosphate They carried out their laboratory experiments under industrial conditions as regards technique.

The conclusions arrived at by the authors were as follows

(1) If 2 molecules of sulphuric acid act upon 1 molecule of pure tricalcium phosphate, only 95 % of the phosphoric anhydride passes into stable monocalcium phosphate, on account of the counter-reaction., If the sulphuric acid is increased so that 3 or 4 molecules act upon 1 molecule of tricalcium phosphate, the yield of monocalcium phosphate is only 98 %, which agrees with the results of previous experiments by MILLOT The counter reaction is more or less promoted by the larger or smaller amount of calcium sulphate present, so that superphosphates obtained from calcareous phosphorites revert more easily.

(2) If the water-soluble phosphoric anhydride in pure monocalcium phosphate is estimated by the ordinary industrial method, in the presence of tricalcium phosphate, its solubility in water decreases with the increase of the tricalcium phosphate, and in proportion to the increase in the temperature. Therefore the more completely the sulphuric acid acts in the lead chambers, the lower is the keeping temperature of the heap of superphosphate, and the less intense the retrogradation process

(3) Increasing amounts of ferric sulphate, in the presence of a constant amount of pure monocalcium phosphate, cause the constant reversion of about 11 % of the soluble phosphoric anhydride, whereas increasing amounts of ferric oxide (between 1 and 16 %) give rise to the retrogradation of from 15 to 52 % respectively, in round numbers.

(4) Ferric sulphate has no action on the reversion of free phosphoric acid, the effect of small quantities (below 2 %) of ferric oxide (estimating the phosphoric acid as monocalcium phosphate, is imperceptible, where-

as the retrogradation continually increases with the amount of the oxide, and reaches 31 %, when the latter is present to the extent of 16 %. This is the reason why, if the phosphorites are rich in iron sesquioxide, and have not been sufficiently acted upon by the sulphuric acid, the monocalcium phosphate and the phosphoric acid present in the heaps of superphosphate largely revert, on account of the residual sesquioxide present.

(5) Aluminium sulphate has no effect upon the retrogradation of either monocalcium phosphate, or phosphoric acid. On the other hand, the presence of clay (in which substance the Florida phosphorites are rich), in amounts varying between 2 to 16 % of kaolin, causes a retrogradation of 14 to 49 % in the pure monocalcium phosphate, and but a slight reversion of the pure phosphoric acid.

(6) The complete disintegration of decreased bone powder (100 parts by weight of bone-ash and 74 of sulphuric acid at 55° Bé), gives an amount of water-soluble phosphoric anhydride which may be as much as 89.7 % of the total anhydride. If the acid is increased slightly, from 5 to 10 %, the amount rises to 97.4 % to fall again slowly, even if the acid be increased. Under these conditions, the amount of the phosphoric anhydride soluble in water and in citric acid remains nearly constant.

(7) The disintegration of prepared bone-ash in the presence of varying quantities of iron sesquioxide gives a superphosphate with a slight regradation (7 %) if the amount of the sesquioxide is 2 %. The process increases rapidly with the addition of the sesquioxide, and reaches 62 % if the latter is as much as 16 %. Under these conditions, the anhydride soluble in water and citric acid also greatly diminishes. Hence the fallacy of the very common idea that the reversion due to the presence of iron sesquioxide has no effect upon the manurial value of the phosphate, provided that the anhydride soluble in water and citric acid remains constant.

(8) Aluminium compounds have no effect in the disintegration of phosphorites.

(9) If during the disintegration of phosphorites with a high iron content, the amount of sulphuric acid is increased to over 90 % by weight of the mineral, the amount of water-soluble phosphoric anhydride in increased, but this does hinder the tendency to disintegration. On the contrary, this process can be modified in one way, namely, by previously mixing ferruginous phosphorites with phosphorites poor in iron, in such a way that the sesquioxide content of the mixture is below 2 % (1).

The authors add that the attempt to improve retrograded superphosphates or those which were badly disintegrated, by means of further sulphuric acid treatment, is quite useless as it only results in the superphosphates being covered with a deposit which makes them difficult to sell.

475 - The Presence of Copper in Plants, and Especially in Food Substances of Plant Origin (1). — Guérithault, B., in the *Comptes rendus de l'Académie des Sciences*, Vol. 171, No. 3, pp. 196-198. Paris, July 19, 1920.

The results of analyses made by the author, given in the appended table prove that copper is constantly present in food substances of plant origin, and no doubt also in all plants. In these experiments the amounts of copper found varied between 8-7 mgm, and 63.6 mgm per 10 gm. of ash, and between 1. 1. mgm, and 17.1 mgm, per kg. of fresh matter. Seeds were found to be particularly rich in this metal.

475 - Composition of Tomato Fruits at Different Stages of Ripening. See No. 505 of the *Review*.

477 - Effect of Light Rays on *Azotobacter*. — Kayser, C., in the *Comptes rendus de l'Académie des Sciences*, Vol. CLXXII, No. 8, pp. 491-493 Paris, February, 21, 1921.

In a preceding article (2) the author studied the effect of different light rays on the 3rd and 6th generation of a culture of *Azotobacter*. He found considerable differences in the bacteria according to the conditions of lighting. In the present paper the author gives the results of the experiments he carried out with the view to determining the extent of the diminution of the assimilating power of the 12th generation, and discovered that this decrease was much affected by the colour of the light to which the cultures were subjected.

478 - **The Phytotechnical Station at Mahndorf, Germany; the Most Important Results Obtained and the Organisation of the Work' especially as regards the Registration of Observations.** — HANSEN, V., in the *Zeitschrift für Pflanzenzüchtung*, Vol. VII, Part, 4, pp. 283-318, 5 fig. Berlin, November, 1920.

The work of the Mahndorf Phytotechnical Station, and the selection experiments that have been made there, or are still in progress, are in many cases of the same character as the general selection work in progress in other parts of Germany and have been carried out on very similar lines. Nevertheless, this Station has certain characteristic features, a description of which may be of interest to agronomists

The experiment fields at Mahndorf are situated at an altitude of about 140 m. above sea-level, and occupy an area of 500 hectares. The soil is composed of the disintegration products of limestone rocks, and of various facies, but open soil mixed with pebbles constitute the commonest type.

The climate, which is somewhat inclement, is very well suited to the type of work undertaken at the Station, for the little snow that falls in winter, coupled with the cold winds that prevail at that season, test the resistance of the plants to low temperatures, while the frequent drought in spring and summer put their other hardy qualities to a severe proof.

So far, the following selected types have been placed on the marked :

Rye
" Dickkopf " winter wheat
" Bordeaux " spring wheat
" Hanna " barley
Oats
" Viktoria " early peas.

Obtained at Mahndorf

VARIETY OF RYE OBTAINED AT MAHNDORF. — This is the result of the selection of " Petkuser " carried out by Prof. REMYS in 1909.

Objects of the selection :— High yield of grain and straw ; high percentage of caryopses ; early ripening : resistance to cold and lodging. The ears should be of erect habit, compact and pointed, square in section, with 19-21 bi-floral spikelets. The presence of spikelets with three flowers is a sign of vigour, but is not desirable for it interferes with the even quality of the grain. The kernels should be greenish-grey, full, elongated, rather large, so that 1000 caryopses weigh from 45 to 55 gm., they should be well covered by the glumes. The average length of the culm is from 140 to 160 ; there are from 4 to 5 nodes ; tillering average ; the best plants have 6 to 10 culms.

This rye produces heavy crops, and is very resistant to cold. The ear, which was originally thin and rectangular, has become more compact through selection, and has assumed an oval, elongated shape The kinds with rectangular ears are also very early in ripening, the straw is short, the kernels are somewhat small, and of a greenish yellow colour On the other hand, the oval, compact ears ripen late, they grow vigorously and have long straw, resist cold well, and the kernels are always greenish-grey.

The best seeds from the different lines, which are separated by careful mechanical selection, are sown separately one by one. If the resulting plants have not the characters desired, they are eliminated, and the seleced types obtained in this way are excellent.

As rye is a staurogamous plant, individuals may appear among the descendants that are distinctly superior to the original stock. In order to be able to make use of these new forms, at all events to a certain extent, some of the finest ears are collected every year from the best lots. These ears are again tested, the finest are definitively selected, and the seeds thus obtained are sown separately, the seeds from each ear being planted in a row by themselves.

DICKKOPF WINTER WHEAT. — Obtained in 1900 from a field of "Mettes Squarehead" by individual selection (by ears).

Objects of selection :— Large grain yield and average straw yield; high grain percentage; resistance to cold, lodging, and rust. Ear ovoid, white, awnless, from 7.5 to 8 cm. long, and consisting of 25 to 28 spikelets. Kernels full and large, weight of 1000 kernels 40 to 45 gm., ; culms of average lengths, 100-130 cm., regular, and with 4 nodes; tillering average; 5 to 7 culms on the best plants.

The characters of this wheat have become fixed, and wild varieties are very rare. It is distinguished by its great resistance to cold, and its heavy yield.

Although *all* the Dickkopf wheat grown at Mahndorf has come from a single plant isolated in 1908, 3 types can, however, be distinguished. The early type has long ears, rectangular longitudinal section, low yield (relatively) and caryopses of average size. The late type is distinguished by the fine ovoid shape of its ears, short culms, and good yield. The 3rd type, now on the market, is of average earliness, the ear is slightly ovoid, the culm of average length, the kernels are large and the yield high.

In 1917, crosses were made between Mahndorf wheat and foreign varieties.

"BORDEAUX" SPRING WHEAT. — Obtained by selection from "Rimpaus Rote Schlanstedter Sommerweizen."

Aims of selection :— High grain yield and average straw production; high percentage of kernels, early ripening; resistance to lodging, rust (*Tilletia Tritici*) and smut (*Ustilago Tritici*). Ears 8 to 10 cm. long, dense, with 17 to 19 well-developed erect spikelets, smooth brownish-red glumes; culms equal, of average height with 3-4 nodes; tillering average, 5 to 6 culms per plant.

This wheat now includes the results of two selection. The products of the first are somewhat late, the ears are erect and almost entirely free from smut, and it is therefore eminently suited for large scale cultivation. On the other hand, the plants obtained from the other selection are earlier, their ears are slightly bent and are somewhat liable to the attack of smut, but their yield is very high, and, as so far no segregation of characters has been observed in them, they are worth further study. In 1919, the products of the two selections were crossed.

HANNA BARLEY has been obtained from the " Kwassitzer Hanna " variety.

Aims of selection :— High grain yield and average straw yield; high percentage of kernels earliness; resistance to lodging and smut. Ears 11 to 12 cm. long; compact, containing at least 30 kernels, which are large, somewhat rough, and weigh 60 to 67 gm. per 1000; culms of average length, 80 to 120 cm., with 5 nodes, without side-shoots; tillering average 8 culms per plant. This barley is an excellent variety for brewing, and as it is very hardy, is adapted to dry districts

Although all the selected plants were derived from a single individual that was isolated in 1907 nevertheless several different types are found among them · — (*a*) A late variety which bears the heaviest crops; (*b*) an early sort with fine large kernels, but liable to lodging; (*c*) a very early kind with small kernels, susceptible to *Ustilago,* but resistant to lodging; as it still shows segregation phenomena, it should be further studied.

MAHNDORF OATS. — Obtained by selection from " Strube-Schlanstedter Hafer. "

Aims of selection: — High grain yield and average straw yield; high percentage of grains; resistance to lodging; full, branched inflorerescence; grains yellowish-white, weighing 40 to 50 gm. per 1000. culm of average length, 120-150 cm., with 3-5 modes. The choice plants should have at least 3 culms.

As regards the number of grains per spikelet, 3 to 4 were formerly preferred, but now plants with bi-floral spikelets are chosen, for it has been found that this reduction in the number ensures better and more complete development of the grain.

Suitable crossings are also being carried out in order to improve the oats.

EARLY "VIKTORIA" PEA. — This has been obtained from a plant of " Strubes gelber Viktoria " which was isolated in 1901. The variety is noted for its early maturity; it ripens 10 days before the original variety but retains it characters of great productiveness.

Aims of selection :— High yield, early ripening, high percentage of seeds, (50-60 %) vigour. The flowering and ripening stages should be regular and short in order to obtain fruits that are similar in ripeness and development. The pods grow in pairs and should each contain 4 to 7 peas which must be very full, large, round, and yellow, with a diameter of 7 to 9 mm., and weigh 300 to 450 gm. per 1000.

The " Viktoria " pea has long been on the market and its characters are very fixed. There are several forms that are all equally stable, the most important being distinguished by the letters M, V, L, and showing the following characters :—

	Seed yield	Size of seeds	Length of flowering period	Ripening
M	good	very large	very long	late
V	average	large	short	average
L	good	small	very long	early

With the view to still further improving this product the forms M, V, and L. have been intercrossed. The following Table gives the results of the examination of the F_2 (harvest of 1919) :—

Analyses of the F_2 *of the different crosses.*

♀ < ♂	Seed yield per plant	Weight of 1000 peas in gm.	Flowering	
			Date of commencement	Duration in days
M × V	13.0	401	June 11	13
M × L	10.6	403	» 5	22
V × M	10.5	384	» 11	29
V × L	10.6	392	» 6	22
L × M	9.8	400	» 7	22
L × V	10.8	380	» 7	30
L × L.	11 1	380	» 6	25

In the cross M × V, the maternal characters are dominant

In the cross M × L, the yield is decreased, whereas the maternal character "large seed" is combined with the paternal characters of early flowering and duration of flowering. In the crosses V × M and V × L, the yield is average and the size of the seed average (maternal characters), whereas the date of flowering is that of the male parent. In the crosses L × M, L × V, and L × L, the maternal characters are dominant.

These forms are still being examined and sorted out with the object of isolating and fixing new types of good quality.

MAHNDORF LUCERNE. — This type is descended from an isolated and self-fertilised plant of Provence lucerne. It has not yet been put on the market. It is distinguished by the development of its leaves and its very soft stem ; flowers fine dark blue ; remarkable for resistance to cold and to rust (*Uromyces striatus* Schroet).

MAIZE. — A number of varieties of maize have also been selected with a veiw to obtaining early maturing varieties with a heavy yield.

POPPY. — In 1918, 2000 early ripening capsules of fine shape were gathered and a few of the best (9.5-6.3 gm, of seed per capsule) were chosen to supply seed for the experiments,

The seeds from each capsule were sown separately in a special row. The offspring differed in development, in length of stem, date of flowering, and the number of capsules per plant so that they provided all that was required for selection. The work was undertaken with the intention of obtaining a type with the following characters: — High yield per plant and per capsule; large percentage of seeds in proportion to the total weight of capsule; early maturity low, strong stalks; white flowers; 3-4 well developed, round capsules per plant; grey seeds.

PEDIGREE REGISTER. — This consists of 3 distinct parts, which are, however, bound together at the end of the year and form a single volume.

On the first page of the first part is given the plan of the experiment field, and the date of the sowing, as well as that of the germination of the seeds, etc. On the succeeding pages are entered observations upon the growth of the plants, and data respecting the harvest, reference being made to individual selection and to each line.

In the second part, are collected all the data referring to the offspring e g., observations made during development, the yield, and the average of the selection data for each plant The third part is the largest; it contains all the observations relating to the characters which are the object of the selection experiments, reference being made in each case to the plants chosen.

---

(1) The first mass selection of the individual plants which is based on the correlation between one or more easily-determined morphological and physiological characters and the economic characters that are the object of the selection, is called the preliminary choice (*Vorauslese*). See FRUWIRTH, *Handbuch der landwirtschaftlichen Pflanzenzüchtung*, Vol. 1, p. 261.

(2) All the plants obtained by this mass selection are subdivided into groups, and the subsequent selection work is carried on within each group. See FRUWIRTH, *loc. cit.*, p. 244.

(1) The total progeny of an individual, or group of individuals

In order to give some idea of the method of registering the data, the following Tables dealing with the winter wheat, oats and peas have been appended: —

TABLE V. — *Selection of oats* 1920.

Plant No.	Culms			Total weight		Percentage of grains	Weight of grains per panicle	White spikelets	Grains		
	Length	Number		Of one plant	Of the grains				a × 50	Weight of 1000 grains	Quality
		Normal	Side-shoots								

(See Tables VI-X on pp. 536-537).

The new registration form is a great improvement on the one used before 1920. On the one hand, it excludes many quite useless entries, on the other, the data given bring out more clearly, the fundamental objects of the work of selection, and facilitate the isolation of the *élites* and best kinds of the plants selected.

479 - **Inheritance of Resistance to Bunt or Stinking Smut of Wheat, in the United States.** — GAINES, E. F., in *Journal of the American Society of Agronomy*, Vol. 12, No. 4, pp. 124-132, tables 8, Washington, D. C., April, 1920.

Investigations on the bunt resistance (*Tilletia Caries*) of 3 wheat varieties : Turkey (Washington No. 326.) Hybrid 128 (Washington No. 592) and Florence (Washington No. 634) and the 2 crosses Turkey × Hybrid 128 and Turkey × Florence.

Notwithstanding its distinct susceptibility to bunt, Hybrid 128 is very prolific, hardy, has a stiff straw and holds the grain well after maturity so that it is grown in large quantities. In 1918, about 2 000 000 bushels of Hybrid 128 were produced (graded commercially as White club), and 100 000 bus. of Turkey which is drought resistant, hardy, of high milling quality (graded as Hard red winter). The straw is, however, not very stiff and the grain scatters easily. It is produced in considerable quantities in the semi-arid districts of Washington.

Florence is a spring wheat of Australian origin (graded as common wheat) : very resistant to bunt.

In the summer of 1915, several hybrids were made between Turkey and Hybrid 128 and between Turkey and Florence. In 1918, the parents and hybrids of F_2 and F_3 were analysed in detail in order to ascertain the percentage of infected plants and of bunt on infected plants with a view to establishing a scale of resistance. The results are given in Table I: —

TABLE VI. — *Selection of peas* (1920).

TABLE X. — *Selection of the poppies* (1919)

Plant Number	Length of stalk	Fruit		Grain		% of grains	Colour of the grain
		number	weight	weight per plant	weight per pod		

TABLE I.

Variety or hybrid	Infected plants	Bunted heads no infected plants	Total bunt produced
	%	%	%
Turkey	3.4	17.7	0.6
Hybrid 128	70.9	63.9	59.8
Florence	5.8	22.9	1.3
F_2 Turkey × Hybrid 128	76.4	47.9	51.0
F_2 Turkey × Florence	20.1	35.5	8.9
F_3 Turkey Hybrid 128	68.3	49.1	50.2
F_3 Turkey × Florence	22.1	45.5	15.4

Turkey × Hybrid 128 showed in F_2 a much high degree of infection than the susceptible parent. This may be attributed to the more vigorous growth of the hybrid which might cause more of the infected plants to survive the winter. On the other hand the percentage of bunt produced on the infected plants is much lower than that on Hybrid 128; the latter condition may be taken as an intermediate condition. The average of the F_3 bears out this supposition.

The F_2 of Turkey × Florence shows a much higher degree of infection than either parent. If resistance is caused by a series of chemical or physiological factors, then two facts are self evident:—

1) Most of the factors for resistance are recessive;

2) Turkey and Florence each have different and distinct factors for resistance.

The author carried out simultaneously a series of experiments with a view to ascertaining the correlation of bunt resistance and morphological characters of wheat plants. Comparisons were made between:

a) *length of spike*: — long bearded, club bearded and intermediate mixed.

b) *beards*: bearded — mixed — beardless.

In the F_3 of Hybrid 128 × Turkey, there appears to be no definite relation between the above mentioned characters and resistance. However, in the case of Turkey × Florence, there is an inverse correlation between bunt resistance and the bearded characteristic.

Very resistant rows existed, however, and numerous gradations between these extremes were found in each morphological type examined, which indicated that existing correlations do not suffice to constitute a solid base for selection of more resistant types.

The F_3 of Turkey × Hybrid 128 produced a continuous series from 1 row as resistant as Turkey to 77 which were more susceptible than Hybrid 128.

The small number of highly-resistant rows indicated a dominance of susceptibility of Hybrid 128. Out of 194 not one of the F_3 rows shewed more resistance than Turkey. There is evidently no single or latent heritable factor for resistance in Hybrid 128. On the other hand, there must be at least 3 independent factors for resistance in Turkey, otherwise there would have been a larger number of rows as resistant as Turkey.

TABLE II. — F_3 of *Turkey* < *Florence.*

Spike characteristics	No. of rows	Plants bunt free	Plants bunt infected	Plants party bunt			Total No. of plants
				Number	Healthy	Infected	
Bearded	38	387	74	90	823	585	**551**
Mixed	78	795	86	112	1017	892	**993**
Beardless	52	421	39	55	442	425	**515**
Total . . .	**168**	**1603**	**199**	**257**	**2282**	**1902**	**2059**

The results obtained seem to warrant the following conclusions: —

(1) Bunt resistance in wheat is not a simple Mendelian unit character.

(2) Resistance, if Mendelian, is composed of multiple factors, for a continuous series ranging from complete immunity to complete susceptibility has been obtained.

(3) Different wheat varieties possess different kinds of resistance.

(4) Linkage between resistance and morphological characteristics is not sufficient to prevent the selection of a resistant strain of any morphological type desired.

480 - **Studies on the Factors and Circumstances Determining the Success or Failure of Crosses Between Wheat and Rye.** — FIRBAS, H., in the *Zeitschrift für Pflanzenzüchtung*. Vol. VII Part 4, pp. 249-252. Berlin, November, 1920.

Results of the study of the biological and environmental factors which petermine the success or failure of experiments in crossing wheat and rye.

1st YEAR. — Hybridisation experiments in which Bokhara wheat was fertilised with the pollen, or mixtures of the pollen, of certain varieties of rye. Bokhara wheat has all the characters of a "population" consisting of various strains having in common the characters of early maturity and rust resistance but differing in some morphological points. Thus, there are awned and awnless forms; the latter, however, are not constant but produce occasionally both awned and awnless plants.

The wheat ears were fertilised with fresh pollen at different times commencing from the date of the flowering stage (when all the glumes, or most of them, have fallen from the ear) until 5 days subsequent to that phase.

Contrary to what had previously been stated, the best results were obtained by fertilising the plants at the time of flowering; a delay of 5 days produces entirely negative results.

In addition to Bokhara wheat the following wheats were used in the crossing experiments. Igel, awned Loosdorfer, Molds Squarehead, red awned Galician (Roter Galizischer Grannenweizen), Czar, Weisser Epp,

TABLE I. — *Results of 1st years' cross.*

State of the maturation of the ear	No of flowers fertilised	No of grains formed	No of seeds germinating	No of hybrids obtained
At the time of flowering	94	30	25	25
One day after » »	98	19	16	16
Two days » » »	90	5	5	—
Three » » »	89	4	4	3
Four » »	81	16	6	6
Five » » »	94	3	2	—

and March spelt. Out of the several hundreds of flowers pollinated, only 2 hybrids were obtained, and were from Roter Galizischer × Rye. Thus the degree of sexual affinity between rye and wheat varies considerably in the case of different varieties of wheat.

2nd. YEAR. — A series of experiments was made with a view to determining the effect of environment, especially of heat, upon the phenomena in question. Comparative experiments were carried out in the open, and under shelter, viz. in greenhouses (at the temperature of the surrounding air or heated), in parchment bags, isolated cylinders etc. None of these environments had any effect upon the crossing results nor were the latter influenced by the age of the pollen.

3rd YEAR. — The first years' experiments showed that the different varieties of wheat varied in their degree of affinity to rye, Bokhara wheat showing the greatest amount. Very great differences were, however, found to exist in this respect between individuals of the same variety.

In the experiments carried out for the purpose of studying this phenomenon, Bokhara wheat was chiefly used ; 12 plants were selected and gave the results set forth in Table II.

TABLE II. — *Results of the Third Year's Crosses.*

Caracters of Wheat plant	No of flowers pollinated	No of grains formed	Varieties of rye supplying the pollen
1) semi-awned	71	5	Askanier, Hanna
2) awned	108	5	Askanier, Hanna
3) awnless	128	17	Hanna, Sperling
4) »	151	10	Petkuser, Tulaer
5) »	65	60	Petkuser, Tulaer
6) »	93	7	Seelhorst
7) »	104	4	Seelhorst, Tulaer
8) »	94	1	Sperling
9) semi-awned	122	3	Tulaer, Petkuser, Sperling
10) awnless	90	1	Zeeländer
11) »	77	1	Zeeländer
12) semi-awned	119	—	Loosdorter

Thus, the individuality of the female parent has a distinct effect upon the results of the crossing; this is especially seen in the case of Bokhara wheat. In that of other varieties, it is much less apparent, as is shown in crosses made with Czar, Red Saxon wheat (Rot Sächsischer Landweizen) and Mold's Squarehead.

481 - **A Brachytic Variation in Maize and its Agricultural Value for Dry Land Cultivation in the United States.** — KEMPTON, J. H., in *United States Department of Agriculture, Bureau of Plant Industry, Bulletin* No. 925, pp. 1-28, pl. XIX, figs. 7, tables, 5, bibliogr. of 14 works. Washington, Febr., 18, 1921.

ORIGIN OF THE VARIATION. — Variations are many in the maize but the brachytic variation deserves special attention, since it possesses several highly desirable features advantageous for dry-land and irrigated conditions.

This variation consists of a shortening of the internodes without a corresponding reduction in their number or in the number and size of other organs. The distinction between this type of variation and ordinary dwarfing is evident. The brachytic strain of maize under consideration arose in a hybrid between the Algerian pop-corn and the Chinese waxy varieties. (No. Dh 416). F_2 was the result of self-pollinating, an F_1 plant being grown for seed characters. Of the plants obtained, 5 were brachytic and 21 normal (1). One of the brachytic plants was self-pollinated and the resulting progeny were all brachytic; at the present time 16 progenies are under observation. Those derived from self pollination gave in F_1 plants as tall as or taller than the normal parent, while F_2 showed a segregation into normal and brachytic plants closely approximating the Mendelian 3 to 1 ratio.

For the Table giving the measurements of maize plants of two sister progenies, one of which was brachytic and the other normal in stature, see prevous article (1).

There are apparently two types of internodes; 1) almost triangular and 2) obliquely truncated cylinder.

Brachytic characteristics have also been obtained by crossing Chinese Waxy and Boone County White (Kansas). F_1, F_2 and F_3 appeared normal; in F_4, however, 2 brachytic plants were found. One of these was self-pollinated, and its progeny offered a striking contrast to those derived from the Chinese-Algerian hybrid. Only 10 plants were grown from this self-pollinated ear, and 9 of them were of normal stature, the other being brachytic. A brachytic plant appeared also in a progeny of the Esperanza variety of *Zea hirta*, this was crossed with a normal plant of the Chinese waxy variety and the hybrid has been designated Mh 17 by COLLINS; neither F_1 nor the following generations showed any evidence of brachysm.

AGRICULTURAL ADVANTAGES. — Brachysm in maize produces a form of plant which seems admirabily adapted to meet the unusual requirements of dry land and irrigated regions, and in addition to this shows resistance to lodging thanks to its sturdy erectness.

---

(1) See *R.*, Oct. 1920, N. 958. (*Ed.*)

With the exception of the Navajo or Hopi type of maize the roots which appear at germination serve only to establish the young seedling; subsequent growth and development depend upon the roots produced from nodes.

In most varieties of maize grown under common cultural methods, from 4 to 8 nodes remain in contact with the ground and produce roots. The uppermost node which produces roots is usually somewhat above the surface of the soil; the young roots are covered with a sticky, transparent gelatinous substance which affords protection from the dry atmosphere and permits them to reach the soil from a height of about 10 cm. (Boone County White variety).

In brachytic plants, the reduction in the length of the internodes results in more nodes coming in contact with the ground, thereby increasing the production of roots, (as much as 40 % over the common varieties). In addition to this increase may be added a further increase of about 15 %, due to the increase in the diameter of the culm.

In irrigated regions the taller varieties of maize lodge badly following irrigation, especially if there is a moderate wind. The brachytic plants are thoroughly anchored and owing to the increased root system, are able to withstand such conditions and remain erect.

Also the reduction in internode length brings the leaves close together, thus effecting a partial shade at the time when the sun is at its height; transpiration is thus reduced and should result in a lower water requirement for brachytic plants.

As a general rule, the commercial varieties of maize are taller than is necessary to satisfy the physiological requirements for yield of grain. The increased height is due almost entirely to the elongation of the internodes and not to an increase in the number of nodes. The brachytic variation affords a means of reducing the stature, with no corresponding reduction in leaf area. There should be no physiological difficulties in combining high productivity with brachytic stature.

Genetically, however, more difficulties are to be expected. Yield of grain, like most quantitative characters is one of those relatively unstable characters difficult to recover from hybrids involving small-eared varieties. If only 10 factors are involved in maximum grain production, all of these would be expected to occur in homozygous combination with brachytic culms in an F_2 hybrid only once in 4 195 304 plants. It is difficult to obtain a combination of good production and brachysm, but it is, however, not unlikely that by crossing a combination of dwarf stature with high productivity of commercial varieties, the value of the strain would be appreciated in area outside the regions of extreme climatic conditions.

INHERITANCE OF BRACHYSM IN HYBRIDS WITH COMMERCIAL VARIETIES. — *Brachytique* × *Boone*. Effort to combine the brachytic character of the culm with the high productivity of commercial varieties. Two crosses were made with the Boone Country White var., and a few of the F_1 plants were self-pollinated; 3 ears resulted and 3 F_2 progenies were obtained. The F_2 plants grown in the field were fully as large as the Boone parent and remarkably uniform.

The F_2 progenies segregated into normal and brachytic plants, 3 : 1 monohybrid ratio , (234 normal and 74 brachytic). The normal plants of the F_2 exceeded the brachytic plants not only in stature, but also in the length of the longest leaf, in the number of rows on the upper ear, and in the length of the ear stalk The brachytic plants, on the other hand, exceeded the plants of normal stature in the number of branches in the tassel, the diameter of the culm, the total number of leaves, and the number of nodes that produce roots.

In yield, as measured by the total ear length, neither the normal nor the brachytic F_2 plants equalled the F_1, but individual plants were obtained which gave a yield equally high, as the best of the F_1 With a sharp segregation into normal and brachytic plants, the procedure to be followed in securing the desired combination of brachytic stature with high yield becomes greatly simplified and eventual success becomes more certain. It is necessary only to cross the best yielding of the segregate brachytic plants with the high yielding commercial varieties and repeat this procedure until the desired combination is obtained.

Brachytic × *Hopi* — The Hopi variety, in common with other varieties, grown by the Indians of the South western States, possesses the long mesocotyl which permits deep planting. An attempt was made to combine the brachytic stature with the deep-planting adaptation. The F_1, was a complete surprise ; the plants were tall but liable to lodging, the ears were small and the yield poor. The F_2 was much better.

Economically therefore, the combination of brachytic with Hopi has been a complete failure and demonstrates the impracticability of predicing the value of a hybrid from the characteristics of the parents.

482 - **Heritable Characters of Maize ; Adherence of Leaves, Bracts and Inflorescences.** — KEMPTON, F. H. (Bureau of Plant Industry, U. S. Department of Agriculture) in *The Journal of Heredity*, Vol. XI, No. 7, pp. 317-322, figs. 4. Washington, D. C., Sept-Oct. 1920.

Adherence is a variation in which the leaves, bracts and inflorescences coalesce. This may occur to a varying extent, and in extreme cases the upper leaves and terminal inflorescences are so firmly compacted into a hardened mass that the parts can not be separated. Frequently the leaves and even husks adhere so firmly to the other organs, that they are ruptured by the force of the elongating plant. and such plants have a characteristic ragged appearance.

Adherent variation was found in the F_2 of a hybrid between Boone County White and the brachytic variety.

Plants combining the brachytic and adherent variations were difficult to propagate, and although the data obtained are few, it seems, not unreasonable to suppose that adherence is a simple Mendelian character recessive to the normal condition

483 - **Behaviour of Hybrids of F_1 *Medicago sativa* × *M. falcata*, in the United States.** — WALDRON., L. R., in *Journal of the American Society of Agronomy.* Vol. 12, Pt. 4, pp. 133-143, figs. 4. Washington, D. C., April, 1920.

Report of determinations made relative to the weight of plants and length of stems of F_1 hybrids secured from crossing *Medicago sativa* × *M. falcata*.

WEIGHT OF PLANTS. — The following table gives the distribution of frequencies of weight in grams of the two alfalfa plants and their reciprocal hybrids.

Group	101–200 gm	201–300 gm.	301–400 gm.	401–500 gm	501–600 gm.	601–700 gm.	701–800 gm.	801–900 gm.	901–1000 gm.	1001–1100 gm.	1101 1200 gm.	1201–1300 gm.	1301–1400 gm.	1401–1500 gm.	1501 1600 gm.	1601–1700 gm.	1701–1800 gm.	Total
M. sativa . .	2	6	24	42	68	68	50	36	17	5	3	1	—	—	—	—	—	322
M. sativa × *M. falcata* .	—	1	1	6	5	5	19	17	15	11	20	8	4	4	4	1	1	122
M. falcata . .	3	28	50	71	57	50	29	28	9	2	1	—	—	—	—	—	—	328
M falcata × *M. sativa*. .	—	6	13	17	24	32	41	23	25	27	16	6	2	3	1	—	—	232

The most outstanding facts about these distributions are: 1) The greater amount of variation among the hybrids than among the parents. 2) The weight of the hybrid is significantly greater than those of the parents *e. g.* — *M. sativa* = 636.8; *M. sativa* × *M. falcata* = 964 4, *M. falcata* = 543.4; *M. falcata* × *M. sativa* = 776 3:

LENGTH OF STEMS. — Significant differences between parent and hybrid are not shown, *e.g.* *M. sativa* = 85.5. *M. sativa* × *M. falcata* = 87.0, *M. falcata* = 80.7, *M. falcata* × *M. sativa* = 87.2.

RESISTANCE TO WINTER INJURY. — The percentage of plants destroyed by winter injury was as follows: *M. sativa* = 7.72, *M. sativa* × *M. falcata* = 6.55, *M. falcata* = 1.04 , *M. falcata* × *sativa* = 3.30.

The resistance of the parent *falcata* is evident from these data. The hybrid behaves as an intermediate in each case, but quite differently in the two reciprocal crosses; the best results are obtained when *M. falcata* is the maternal parent

484 - **A Vetch Plant with Lentil-Shaped Seeds in Czeco-Slovakia.** — FRUWIRTH, E , in *Zeitschrift fur Pflanzenzuchtung*, Vol VII, Part 4, pp 356-362, 1 fig. Berlin, November 1920

In the Botanic Garden of Chlumetz, in the winter 1919-1920, a plant was observed growing in a bed of lentils (*Ervum Lens*), which in appearance and habit entirely resembled a vetch (*Vicia sativa*), with the exception, that its seeds were flat and similar in structure to those of the lentil.

A like occurrence had already been noted by Prof. LEGANY at Magyaróvár, by SCHREYVOGL at Loosdorf, and by WIEGMANN.

The author carefully studied the progeny of the Chlumetz plant to the second generation. It was at first supposed to be a natural hybrid of *Vicia sativa* and *Ervum Lens*, but the following facts are at variance with this theory:

1) These hybrids could not be obtained artificially; 2) the Chlumetz plant, which should have been a hybrid of the F_1, except for the aberrant shape of the seed, was in every respect a vetch; 3) in the 2nd generation, there were no segregation phenomena, the shape remained absolutely constant, and the plant transmitted its unaltered characters to its descendants.

Since the probability of its being a spontaneous variation is also excluded, the author concludes, that the Chlumetz plant and its progeny form a pure line of vetch.

Hitherto, cultivated vetches have not been systematically selected, and form populations composed of a mixture of forms; amongst the latter, plants bearing more or less flat seeds are by no means rare. By the selection of extreme cases, it would be easy to isolate types of vetch with seeds shaped like those of the lentil.

485 – **Experiments in Self-Pollinating and Cross-Pollinating *Hevea brasiliensis* in the Dutch Indies.** — HEUSSER, C., in the *Mededeelingen van het algemeen Proefstation der A. V. R. O. S.*, year V, No. 1, pp. 1-6. Medan, January, 1920.

The improvement of *Hevea* in chiefly based upon the vegetative propagation of trees selected as likely to supply the best scions.

Nevertheless, the question has arisen of late as to the possibility of obtaining good results in this direction by means of crossing and selection.

There are two ways in which this work may be carried out: — 1) By using the best individuals, of the filial generation for subsequent crossing, with the object of fixing (by means of transmission through succeeding generations) the best types, that is to say, those possessing the best combination of characters; 2) by obtaining grafts of superior quality from the selected hybrids.

The present report contains the results of many experiments in self-pollinating and cross-pollinating.

CROSS-POLLINATION. — Twenty suitably-chosen trees were used for this purpose, 30 different crosses, being made. Out of a total of 6710 operations, 730 (10.8 %) gave positive results, 2186 seeds being obtained.

The highest percentage of fruit set was in the cross ♀ 138 × ♂ 146, with 83 fruits resulting from 211 pollinations (39.4 %). The crosses ♀ 164 × ♂ 144: ♀ 29 × ♂ 141; ♀ 139 × ♂ 146, and ♀ 139 × ♂ 26 gave entirely negative results

In the course of the experiments, it was observed that the fertility of the female parent is a very variable character, and further, that the number of fruits formed on the same tree differ according to the nature of the tree from which the pollen is taken.

Thus, when the female parent 157 was crossed with Nos. 161, 166, 164 and 161, the percentages of fruits set were respectively, 2. 4, 7, 14.7 and 8.1

SELF-POLLINATION. — This was effected on 6 trees. In the case of 4 out of the number, the results was entirely negative ; the 5th produced but one fruit, although as many as 170 flowers were pollinated ; as for tree 164, out of 131 pollinations, only 9 were successful.

This is a confirmation of the fact that *Hevea* is normally staurogamous, and that self-fertility can only be induced if the greatest precautions are taken.

The following Table gives the data of the experiments.

		Pollinations						
	Date	No of flowers	No of branches	No of fruits set	Percentage of fruits set	No of seeds obtained	No of germinating seed	Female parent Average daily yield in 1919
142	10 Feb. and 12 Mar.	220	45	—	—	—	—	107 cc of latex
164	22 March .	131	18	9	6.9 %	30	28	141 » » »
36	9 May . . .	135	84	—	—	—	—	80 gm rubber
49	25 May	232	98	—	—	—	—	33 » »
138	15 May	306	50	—	—	—	—	41 » »
174	12 April	170	40	1	0.59 %	3	3	38 » »
	Totals . . .	1 194	335	10	0.8 %	33	31	

The fruits of tree 164 furnished 30 seeds, of which 28 germinated regularly. The development of the seedlings was most carefully watched, to see if there were among them types giving a large yield, and at the same time endowed with great self-fertility, which would much simplify the work of selection as regards line 164.

486 - **The "Herald", New Variety of Prune in America Originating Probably from *Prunus Munsoniana* by Mutation.** — DETJEN, L. R., in *The Journal of Heredity*, Vol. XI, Pt. 6, pp. 253-258, figs. 5. Washington, D. C., July-Aug., 1920.

The tree described is growing in the garden of W. F. MARSHALL in Raleigh N. C., and had been purchased from the Stark Bros. Nursery Louisiana (Mississipi) under the name of "Milton plum," as belonging to the *Prunus Munsoniana* Wight and Hedrick species.

The following are the special characteristics associated with the "Herald" compared with "Milton"

1) The stem is attached to both branch and fruit which prevents the latter from dropping to the ground as soon as ripe, and instead they dry naturally in the sunshine and wind ;

2) The leaves are somewhat small ;

3) The petals are rather larger (the corolla measures on the average 17 mm) ; compared with 13 mm. (Milton).

4) The pit is larger in dimensions than that of the Milton ;

5) Milton variety grafted on *Prunus angustifolia* took well and grew vigorously, whilst " Herald " proved less vigorous, and died off early

It is of interest to note the effect a different stock, *Prunus angustifolia* exerts on the Herald variety; the fruits and pits diminish in size, and the surface of the fruit is velvety like that of *P. angustifolia*, unlike the hard characteristic of the Herald fruit.

The author believes that the existence of the Herald variety may be attributed to mutation arising from the native *Prunus Munsoniana* This mutation as already noted possesses the advantage of producing fruits which dry and shrivel as readily as the European types, but cannot be expected to compete with any of those owing to the soft and juicy texture. However, it should be possible eventually to obtain by crossing with the best commercial varieties, a new type combining the characteristics of the fruit of *P domestica* with resistant and late flowering qualities, which could be utilised with success in eastern America, where the climatic conditions and fungoid diseases at present hinder the growing of commercial varieties.

487 - **New Society for the Production of Selected Seeds in Zagabria (Yugo-Slavia).** — *Zeitschrift für Planzenzuchtung*, Vol. VII, Pt. 4, pp 367, Berlin. Nov., 1920.

On January 1, 1920, a Society was founded in Zagabria which proposes to encourage the production of selected seed throughout the Serbian, Croatian and Slovac Empire. This Society possesses an experimental field where various kinds of crops are cultivated and selected. The propagation of the types and varieties thus obtained is put into the hands of Members of the Society.

Prof. V. MANDEKIČ has been nominated as consulting expert of this Society.

488 - **Studies on Sorghum Seed ir Wisconsin. U. S.** — See No. 471 of this *Review*.

489 - **Wheat-Growing Experiments in the Province of Turin, Italy.** — BOCHICCHIO, in the *Italia vinicola ed Agraria*, Vol. XI, No. 10, pp. 159-150. Casale Monferrato, March, 6, 1921.

Experiments carried out on the estate of the Royal Agricultural College of Caluso (Ivrea region, Province of Turin), in 1920.

The following varieties of wheat were sown broad-cast on fairly compact soil in the second half of November and manured with superphosphates The appended Table gives the resuts obtained.

Varieties	Yield of grain in Kg. per hectare
1) Red Canavesano Wheat	973
2) Hybrid Gentil rosso × Noé	1164
3) Carlotta Strampelli	1250

On another area where the soil was light, the wheat was sown with drills an December 3 and manured with superphosphate, with the following results:—

Varieties	Yield of grain in kg. per hectare
1) Semi-awned Gentil rosso wheat	944
2) Hybrid Gentil rosso × Noé	940
3) Early Piedmont Wheat	970

Carlotta Strampelli may be said to have stood the test well, seeing that the season was bad, and the ripening of the wheat had been much hindered by scorching.

The author does not share the opinion of wheat growers who consider this variety to be subject to lodging and dissociation of characters, but he considers that it is necessary to grow earlier varieties in Piedmont amongst which " Early Piedmonte " (obtained by Prof. JACOMETTI by crossing) in worth mentioning. The hybrid Gentil rosso x Noé obtained by PASSERINI is very adapted to late sowing; semi-awned Gentil rosso did not give satisfactory results. Canavesano wheat never gives very high yields, but it is especially suited to damp, compact soils.

490 - **Field Experiments with Maize in New South Wales 1919-20.** — CLAYTON, E. S. in *The Agricultural Gazette of New South Wales.* Vol. XXXVI, Pt. 1, pp. 1-6. Sydney, Jan., 1921.

Report of experiments conducted at the Grafton Experiment Farm 1919-20 on black alluvial soil.

I. — HILLING VERSUS FLAT CULTIVATION. — The plot hilled with the disc cultivator presented a cleaner appearance and damaged fewer roots than in the case when hilled with the plough. None of the plants showed any tendency to lodge and the main benefit derived from the hilling was the burying of the weeds in the rows. The following shows the comparative yields per acre according to the different treatments: — hilled with disc cultivator 48 bus. 41 lb; flat cultivator, 44 bus. 42 lb; hilled with plough 42 bus. 19 lb.

II. — " DE-SUCKERING " *i. e.* REMOVAL OF SUCKERS. — The experiment was carried out on two plots, each ½ acre in area. It was estimated from the results that 1 ton of greenstuff per acre was obtained by the de-suckering. As however the untreated plot yielded 70 bus. 34 lb. and the treated plot 69 bus. 55 lb. the loss of maize amounted to 35 lb.

III. — DEEP VERSUS SHALLOW CULTIVATION. — The plot receiving deep cultivation (5 in. deep) presented the cleanest appearance throughout but the roots of the maize plants certainly seemed to be damaged, especially toward the later stages of growth during the process. This was clear from the yield per acre (39 bus. 10 lb.). The plot receiving deep cultivation (5 in.) till the plants were about 15 in. high and than shallow cultivation (2 to 3 in.) until tasselling, gave very simular results (43 bus. 16 lb. per acre) to that obtained with shallow cultivation throughout (42 bus. 48 lb.). The crop sown in November 19, was harvested the following August 20.

IV. — GREEN MANURING EXPERIMENT. — Grey field peas, rape, and vetches were the green manure crops tried, sown at the rates of 12 lb., 1 ½ lb. and 10 lb. per acre respectively. The land had previously been occupi ed by a wheat crop. The following results were obtained:—

	Yield per acre	
	bus.	lb.
Maize with rape sown at tasselling stage	69	52
» » grey field peas	68	11
» » vetches	63	25
» » alone	66	30

V. — LATE CULTIVATION. — An experiment carried out with the idea of comparing the yield of maize cultivated up to tasselling time with that of maize receiving only one cultivation after hilling. The preparation of the land and the details of sowing were identical with those of the suckering experiments. The first mentioned method gave the more satisfactory results, 68 bus. 36 lb. per acre compared with 63. bus. 16 lb.

VI. — RATE OF SEEDING. — Two varieties of maize were used: — Leaming and Improved Yellow Dent. The former was sown at varying distances apart at the rate per acre of 6.5 lb. 8.1 lb. 9.3 lb., and 13 lb. and the latter at 8 lb., 10 lb., 11 ½ lb., and 16 lb. per acre.

In both experiments, the lowest rate of seeding gave the lowest yield. In the Yellow Dent var. the highest net gain per acre was obtained from the heaviest seeding, namely 16 lb. of seed per acre. In the Leaming var. the highest net gain was obtained from the second heaviest seeding, namely 9.3 lb. per acre.

491 - **Employment of Agricultural Machinery in the Cultivation of Rice in California.** — APOSTOL, S. (Chief Plant Industry Division Philippine Bureau of Agriculture), in *Bulletin Agricole de l'Institut scientifique de Saigon.* Year III, No 1, pp 1-3. Saigon Jan., 1921, and *The Tropical Agriculturist,* Vol. LVI, No. 2, pp. 86-87. Peradenya, Ceylon, Feb, 1921.

The author has recently completed an extensive tour of most of the principal rice growing countries of the world, and has chosen this subject in view of the tendency in many such countries to adopt modern methods of cultivation. He keeps in view throughout the special climatic conditions of California, and confines himself to a simple exposition of the actual methods observed by him during his visit, leaving the reader to make his own deductions as to their practicability under other and different conditions.

Up to the present time the cultivation of rice in California has been confined to the broad valley of the Sacramento, which is exceptionally favourable to the employement of modern agricultural machinery. In practice this is often of considerable power and weight. Multiple ploughs, often with 8 or 10 shares are employed for working the land. On one occasion a specially heavy single-shared plough, drawn by a pair of 75HP tractors was seen in action breaking up the bunds before the general working of the land commenced.

Harrowing and reconstruction of the bunds are also carried out by mechanical methods. Transplanting is not practised; in its place large seed drills are employed. Weeding is the only occupation carried out by hand, and for this the labourers. —. many of them Asiatic — receive a daily wage of from 3 to 4 ½ dollars.

Threshing is done in the field, when all the sheaves within a radius of about half a mile are carried in specially constructed waggons, to the threshing machine, and when all these have been threshed, the machine is moved further on.

The grain is often transported in sacks of " burlap " or " gunnies " direct from the field by means of motor lorries or in trains of trailers drawn by tractors. The 4 wheel drive tractor is especially esteemed for this class of work.

The exceptionally favourable topography permits the establishment of large square fields of 5 to 15 acres — often of 30 acres or more — thus facilitating the employment of large machines. Apart from this, and the many other local considerations especially favourable to the use of machinery, the extremely low rainfall (21.3 inches per year) is very significant. The author gives a table showing the average rainfall per month and per year covering a period of 10 to 46 years ending in 1916 for the Sub-Stations of Biggs, Chico, Colusa, Durham, Gridley, Marysville and Willow, in the Sacramento Valley. The monthly average is 45.2 mm. and the yearly average 542.8 mm. The rainfall is heaviest in December and January.

The land is worked immediately after the harvest in October, and the beginning of November. The frosts and thaws of the winter months make subsequent harrowing easy. The final working of the land is completed in March and April. The first day of April is considered as the commencement of the sowing season which continues up till the beginning of June, although it is estimated that the best results are obtained when the seed is sown not later than May 10.

The fact that all the cultural operations can be carried out during months when the rainfall is slight (average of 42-2 mm. November, February to May), together with the admirable irrigation and drainage systems which allow the soil water to be controlled, will account for the ease and efficacy with which agricultural machinery is employed.

492 – **The Influence of Size and Character of Seed on the Yield of Potatoes.** — SALAMAN, R. N., in *The Journal of the Ministry of Agriculture*, Vol. XXVIII, No. 1, pp. 43-48, tables 4. London, April, 1921.

In 1920, a preliminary investigation of the above problem was begun. For this purpose a stock of a new variety (1) was employed which had been grown in Barley, Herts, the previous year; the tubers had been clamped during the winter and sprouted in the spring.

---

(1) This potato is not, as yet, on the market. (*Author's note*).

This main crop variety was well adapted to this type of experiment for two reasons: it is an exceptionally heavy cropper and it is extremely resistant to leaf roll and mosaic disease. The tubers are white kidney and are immune to wart disease.

Selections of the seed tuber were made by the author according to various grades, and the number of tubers in every found weight of seed was carefully checked. The tubers were selected both for size and weight so that each class was as uniform as possible. The classes selected were — 1) 0.4 oz., 2) 1.3 oz.; 3) 2 oz.; 4) 2.6 oz.; 5) 4 oz.; 6) 5.3 oz.; 7) 5.6 oz.; 8) 6 oz; 9) mixed seed of all sizes

The results of the experiments so far as this first year allows of conclusions, are: —

1) That although small chats give a big return in proportion to their weight as seed, and produce as much, in this experiment even more, big ware than any class of seed, yet it is certainly not economical.

2) The best seed class are tubers of 2 oz. in weight and these give the best returns, excepting the large tuber sets with secondary growths.

3) Seed tubers over 2 oz. in weight give smaller crops whilst the amount of seed is progressively greater. The amount of heavy ware is progressively less, both actually and relatively.

4) The tendency to secondary growth formation is not conveyed to the crop from the seed tuber. It is a peculiarity of big tubers and is not directly influenced by the size of the seed tuber. That the sets with secondary growth should have proved such successful seed is, however, not surprising as they naturally indicate a high vegetative activity on the part of the parent tuber, which experience has long shown to be the best type of tuber seed. Seed tubers with secondary growth make exceedingly good seed, and apart from the fact that they are large and wasteful without cutting, the evidence would tend to show that their use as seed is strongly indicated.

As the value of a potato crop is concentrated in the main on the quantity of the large ware size tubers formed, it is of interest to refer to the table where the percentage of the entire crop represented by the tuber of 4 oz. and over is shown. The highest value, 73 % of the total crop is given by seed tubers of less than 1 oz. in weight. *i. e.* by chats., so that it would appear that the larger the set, the smaller the quantity of big ware. When, however, the fact is taken into account of the bigger crop from the 2 oz. sets, the total yield per acre of large ware is considerally greater in this than in any other class. It, however, cut tubers with secondary growth will yield in the same manner as the large ones of class 8, then the advantage of such sets might at least equal that of the 2 oz. set in the production of heavy ware

The crop of a potato plant must be expressed in the quantity of tuber material produced, and its subdivision into tubers depends on other factors and is probably influenced by environment. The general approximation of the numbers of tubers in the classes of the crop from mixed seed, with that of the average of the 8 seed classes, is a fact of considerable interest (See tables).

493 - **The Production of Alfalfa Seed in New South Wales.** — WHITTET, J. N., in *The Agricultural Gazette of New South Wales*, Vol. XXXII, Pt. 2., pp. 105-112, pl. 16. Sydney, Feb. 1921.

Within recent years the cultivation of alfalfa has spread to the drier parts of New South Wales, and good results have been obtained from Bathurst, Coolah, Canowindra, Binnaway, Coonabarabran, and Pallamallawa districts, with both crops and also seed.

The method recommended for planting in the drier parts of the State is to sow the seed in drills 30 to 36 in., apart, in order to maintain a friable surface soil by hocing between the rows.

The varieties tested at the different experiment farms in these dry districts were selected from the best local strains and also introduced varieties; amongst these were included: Tamworth Broad Leaf, China (from the Pekin plains), Cossack, Semipalatinsk, Kansas, Montana, and Grimm (from U. S. A.) Variety Grimm had given excellent results in the United States as the most superior alfalfa in respect to winter hardiness. Montana is also extremely resistant to frost, and appears to suit the cold regions of New South Wales better than var. Grimm.

In the most satisfactory alfalfa growing districts the general rate of sowing is 15 lb. per acre but as much as 20 lb. is occasionally used, with a view to obtaining a fine stemmed for hay. Germination tests in the Department's Laboratory extending over a number of years show an average of 80 %, but this does not include the hard seeds. If the seed coats of the latter are scratched before planting, the majority of them will germinate successfully. Good results have been obtained by lightly rubbing the seed on a rough surface, such as that of an ordinary fine brick. Tests are still in progress to obtain data as to the length of time the untreated seeds, which failed to germinate after 14 days under cover, will take to germinate after being allowed to dry and then sown in soil. The following results are interesting from the point of view of rapidity of germination: — which is an important consideration from the farmer's point of view.

Percentage of germination total in 7 days.

	Sample		
	1	2	3
Hard seed not scratched	16 %	20 %	4 %
» » scratched	96	70	84

A fairly high standard of purity has been maintained by alfalfa growers and importers according to the particulars obtained from the seed testing laboratory records here reported. A list of the common weed seeds is given, and instructive identity photographs are given of the seeds: — *Centaurea melitensis, Plantago lanceolata, Carduus lanceolatus, Chenopodium album, Setaria viridis, Paspalum dilatatum. Cynodon Dactylon. Melilotus parviflora, Cuscuta Trifolii, Polygonum aviculare, Rumex Acetosella, Carex paniculata, Rumex crispus*, Shrivelled alfalfa seed, hard alfalfa seed, and normal alfalfa seed.

C. Dactylon, P. dilatatum and *P. distichum* are three of the very worst pests in an alfalfa field as they not only crowd the alfalfa plants but cause considerable trouble to the mowing machine.

The December cutting is generally reserved for seed purposes, and should be harvested when the majority of pods are yellow. When harvesting small areas, the crop should be cut with a scythe, and if a mower is used, a swath-board should be attached. If a reaper and binder is employed, the sheaves should be piled into shocks and stand for 5 to 10 days and allowed to become throughly dry before stacking and threshing, or properly adjusted so as not to bind the crop, but merely drop it into heaps by means of the sheaf carrier.

Stacking should be made in a manner similar to that for alfalfa hay, building it with a good foundation of straw. Small quantities are threshed with a flail, but alfalfa seed threshers are also available.

Four to 8 bus. per acre of seed are obtained in a favourable season on good quality alfalfa land, on medium class land, 2 to 3 bus.

494 - **Factors that Affect Alfalfa Seed Yields.** — BLINN, P. K., in *Colorado Agricultural Experiment Station Bulletin* No. 257, pp. 1-32, figs. 27. Fort Collins, Col., 1920 (résumé in *Experiment Station Record*, Vol. 44, No. 3, p. 230. Washington, 1921).

Experiments made in cooperation with the Office of Forage Crop Investigations of the U. S. Department of Agriculture, concerning seed setting tendencies of the different strains and the effect of seed selection on improvements of seed yields; moisture requirements, irrigation, cultural and spacing tests; observations on the relations of insects, climatic conditions, and soil fertility on alfalfa seed production.

The conclusions may be summarised as follows:— A difference in the inherent seed-setting tendency of different strains of alfalfa was noticeable, the southern strains, particularly from Ecuador, Peru, and Tripoli appearing to be strongest in this respect. These are not considered adapted to the climatic conditions, lacking hardiness. Although seed selection for prolific seed yield improved the ability of the selected stocks to produce seed yields, the improvement is not thought sufficient to solve the problem.

The amount of moisture for alfalfa seed production should be so regulated that a minimum amount of forage growth will result and still have sufficient moisture to mature the seed. Making a pasture of the first growth late in the spring has apparently stimulated good seed yields, and this seems to be coupled with a system of irrigation such as to regulate the amount of water and hold it close to the minimum requirement by having small irrigation furrows about every 30 in,

A thin uniform stand, about 1 plant to 1 or 2 sq. ft. is advised to ensure good seed yields. Growing alfalfa in rows is not recommended chiefly on account of the difficulty in handling the crop,

But very little evidence that bees are essential to alfalfa seed yields is at hand. Dry climatic conditions with high temperatures seem to be among the most essential requirements for successful production. It appears that excessive quantities of soil nitrates possess deleterious effects on seed yields in many irrigated regions reserved for alfalfa.

495 - **The Use of *Saccharum biflorum* as a Forage Plant in Algeria.**— GUIGNARD. Paper presented at the Meeting of the Academie d'Agriculture, held on March 23, 1921., in the *Comptes Rendus des Seances de l'Académie d'Agriculture de France*, Year 1921, Vol. VII, No. 12, pp. 308-311. Paris, March, 1921.

Dr. TRABUT communicates the results of experiments made on the coast of Oran, with the object of fixing the sand dunes by planting *Saccharum biflorum* (1). The experiments carried out in the dunes of Bon Hacheria, and on the Gay estate at Khemis, were eminently successful. *Sacc biflorum* proving to be useful not only as a wind-break and a fixer of moving sands, but also as an excellent forage plant.

According to information received from the chief Inspector of the Waters and Forests, the first cuttings were planted at the end of 1919, 50 cm. apart and in lines at intervals of 5-10 m. in rectangles prepared in the dunes of Bon Hacheria. These plantations are now 1 m. wide, and the plants have attained the height of 4 metres, forming a dense growth. Wherever the sands have collected near the lines, the width of the plantations has still further increased; owing to the contact of the stems with the soil, adventitious roots have been formed at each node, thus forming new growing points. It has been found that other Gramineae which have been used with success elsewhere (varieties of *Ricinus*, Takaout (*Tamarix articulata*), and other varieties of *Tamarix*) are here only auxiliaries that can well be dispensed with, as their effect is of little account as compared with that of *Saccharum*.

With regard to the use of *Saccharum biflorum* as a forage plant GAY, the Colonial correspondent of the Botanical service, sends the results of the following experiments carried out at his farm on the coast:—

Cuttings 30-40 cm. long were set 50 cm. apart; the plants soon spread over the intervening spaces, and formed an unusually luxuriant meadow. *Saccharum* shoots again immediately after cutting, and is able to furnish several crops a year. It should be planted in the spring, but cuttings take root at any season Animals had been found to eat the plant with avidity, therefore it was used on a large scale as a stock feed during the recent period of scarcity. It sufficed to keep 36 horses and mules, and 42 oxen in perfect condition, so that they never missed one day's work. The foliage was ted in its natural condition, and the stems were cut up and chopped with a vine-cane breaker.

---

(1) See *R.*, Feb. 1921, No. 158. (*Ed.*)

The composition of the plant is as follows:—

	Per cent.
Water	74.8
Albuminoids	2.4
Fats	0.45
Nitrogen free extracts	13.4
Crude fibre	0.48
Ash	2.45

From what has been said, *Saccharum* might be planted with advantage on the sands of French regions bordering on the Mediterranean, but it is in West Morocco that it would render most service.

496 - **Yield and Quality of Hemp in Wisconsin, U. S.** —See No. 471 of this *Review*.

497 - **Indian Jute (*Corchorus* spp.).** — Mc Leod Sir Chas., in *The Asiatic Review*, Vol. XVII, No. 50, pp. 302-306. London, April, 1921.

Jute in India, can be grown in almost any soil which has a good depth and the necessary material required for fertilisation. On the alluvial soils in Eastern Bengal, jute grows freely without any artificial help. On the other hand the higher lands are heavily manured and yield heavy crops, not only on this account, but also owing to the fact that the jute has better chance of ripening on land immune from floods. Early in February, the ploughing commences on low-lying lands, and continues until the beginning of May on the higher lands.

After the land is ploughed and pulverised the seed is sown broadcast, in quantities of from 6 to 12 lb., per acre. The two principal species cultivated are *Corchorus capsularis*, and *C. olitorius*. The former is easily distinguished by its round pods, while the latter has long cylindrical pods, which are more easily decorticated than *C. capsularis*, and this is a distinct advantage although the last mentioned can stand submersion better, and generally speaking is less easily affected by adverse climatic conditions. Notwithstanding these peculiarities, it has been proved beyond all doubt that each of these species would yield a different class of fibre if subjected to different conditions of soil and climatic influences.

The period of harvesting varies according to the district, and starts earlier in the lowlands than elsewhere. Early cut jute is however never very satisfactory; it is usually immature, short and mossy. The process of "retting" usually takes anything from 10 to 35 days according to the time of year. In July and August, when the temperature of the water is high, the process is quicker, and the jute is ready for further handling, but in September and later, it takes quite a month to "ret" the plants. After retting is completed, the plants are taken out of the water, the fibre extraced, washed, and dried, and when sufficiently dry, it is rolled up in drums, and sent to the nearest market or sold locally to small dealers, who take it away to some of the large centres and dispose of it at a considerable profit.

The use of jute presses in the jute districts has greatly facilitated transport. These are used to pack what are known as "cutcha" bales, containing 3 to 3 ½ maunds*. The exported bale to Europe and other countries is of a fixed standard of 5 maunds or 400 lb. The packing is chiefly done in Calcutta.

Normally, jute is the cheapest fibre for providing bags to carry the produce of nearly the whole world. It carries all the valuable wool and grain from the various countries where grain and oil seeds are produced. Other uses are also enumerated by the author including several uses locally in the jute districts of India, and also its utilisation for the making of sand bags during the war.

498 - **Plants Suggested for the Manufacture of Paper in Various Countries** (1). — I. South African Grasses for Paper Making, *Bulletin of the Imperial Institute*, Vol. XVI, No. 2, pp. 127-134, London. 1918. — II. Tropical Grasses as Paper Making Materials (Fed. Malay States of Australia). *Ibid.* Vol. XVI, No. 3, pp. 271-275, 1918. — III. PEARSON, R. S., The Manufacture of Paper Pulp from Bamboos in India, in *The Indian Forester*, Vol. XLVI, Nos. 11 and 12, pp. 547-565 and 603-631, pl. 3. Allahabad, Nov. and Dec., 1920. — XI. Utilisation of Bamboos for Paper Making in Various Countries (India, Ceylon, Indo-China, China, Japan, Philippines, Malaysia, Dutch E. Indies, Australia, America, Brazil, W. Indies, Africa, Madagascar), *Bulletin of the Imperial Institute*, Vol. XVIII, No. 3, pp. 403-427. London, 1920.

I-III-IV. — SOUTH AFRICA (2). It has long been realised that the tropical countries possess in their coarse grasses, abundant raw material for the manufacture of paper. A number of grasses have been sent to the Imperial Institute from South Africa for trial, and a selection of the reports is here given: —

a) *Sorghum halepense* (3). — This grass gives a good yield of pulp, but is nevertheless not very promising as a paper making material. The pulp contains a large amount of parenchyma derived from the pith, which renders the paper parchment-like. This might however lend a possibility for the production of special kinds of parchment like papers either by itself or mixed with other fibrous materials.

---

* 1 maund = 82.28 lb.

(1) See also *R.*, April 1921, No. 436. *(Ed.)*

(2) See *R.*, Aug. 1918, No. 869.

(3) See *R.*, Feb. 1920, No. 202. *Ed.)*

b) *Andropogon* spp. — 1) A sample of "thatching grass" or "Dek Gras," identified as *Andropogon Buchanii.* Stapf, received in 1917. In every case the pulps furnished an opaque paper of good strength and quality, which did not shrink appreciably on drying, and appears a promising material for the manufacture of strong brown paper, or after bleaching, for other purposes. — 2) *A. Dregeanus*, Nees, and *A. auctus* Stapf "Tambookie Grasses." Both samples gave good yields of unbleached pulp, which produced tough, strong papers of good quality. — 3) *A. hirtiflorus* var. *semiberbis* Stapf — This grass give s a good yield of pulp but the ultimate fibres are short and the paper produced is somewhat inferior is strength to that yielded by the aforementioned species. It would however be quite suitable for the manufacture of paper pulp on a commercial scale.

c) *Trachypogon polymorphus, Cymbopogon Ruprechti* and *Cymbopogon* sp.(1). — These grasses give very good yields of pulp which compare favourably with the yields obtained from esparto grass (*Macrochloa tenacissima*) under similar conditions. *T polymorphus* is found in tropical and sub-tropical America, and Madagascar, and in South Africa is known as "steek" grass.

d) *Themeda Forskalii* var. *mollissima.* — Yields a pulp giving a strong opaque paper which does not shrink appreciably on drying. The nodes of the grass are however harder than those of "tambookie" and "dek" grass, and would necessitate a through boiling and beating in order to break them up completely and obviate the presence of yellowish specks in the paper.

e) *Tristachya Rehmanni.* — Common in the Transvaal High Veld. — The shortness of the ultimate fibres rendered an inferiority in strength to the opaque paper obtained. It might however be utilised locally in admixture with better materials, such as *Andropogon* spp.

f) *Panicum obscurans.* — Common on the High Veld. On account of the presence of small bracts, and their effect on the paper produced, this grass is decidedly inferior as a paper making material to most others from South Africa put to the test, and would probably only be suitable for the manufacture of cardboard or brown paper.

g) *Aloe dichotoma* "Kokerboom," — Found in Namaqualand. One of the largest of the South African aloes, reaching a height of 15-25 ft. or more with a trunk 2.3 ft., in diameter at the base. On removing the bark and leaving to dry in the air, it was found that 100 parts of the original stem yielded 21.4 parts of air-dried decorticated material. The ultimate fibres were of good length (2 to 4.4 mm.), but were rather coarse and harsh. Results on the whole show that kokerboom is not a promising paper making material. The pulps produced give a fairly strong opaque brown paper which however could not be bleached.

III. — RHODESIA. — *Ricinodendron Rautanenii*, "Mungongo." — Results of examination of the wood samples received showed that this wood is not a promising material for the manufacture of paper pulp by the soda process but it is possible that pulp, of a somewhat better quality might be obtained by the sulphite process.

---

(1) See *R.*, Nov. 1916, No. 1162.

[498]

"Mugugubova Bark." It is improbable that this bark could be remuneratively exported but might be utilised locally for paper manufacture.

IV. — BRAZIL. — The Aninga plant (*Monthrichardia arborescens*) occurs abundantly in parts of Brazil, and considerable attention has been paid in recent years to the possibility of extracting the fibre for use as cordage material and utilising the stems as a source of paper pulp. Results show that the stems would yield a pulp furnishing a good brown paper, but cannot be bleached sufficiently for writing or printing purpose.

III. IV. — EGYPT. — a) *Cyperus alopecuroides*. — The stems give a fair yield of moderate quality. By fairly drastic treatment (*e. g.* 20 % caustic soda) a pulp yielding a fairly white paper of moderate strength can be produced, and the removal of parenchyma by washing would probaby improve the quality although decreasing the pulp yield; suitable for native use. b) *C. Papyrus* Moderate yield of pulp of fair quality; pulp suitable for brown paper can be prepared from stems by mild treatment. Inferior to *C. alopecuroides*, but suitable for use locally. Mature specimens are richer in cellulose and give a higher yield of pulp than young stems.

c) *Typa* sp. (Burdie Grass). — Moderate quality pulp, but suitable for production of brown wrapping paper or cardboard: did not bleach well: — suitable for local use only.

II-III-IV — AUSTRALIA (1) NEW ZEALAND, PAPUA, NORTHERN TERRITORY, FIJI. — a) Bamboo grass (2) from the N. Territory gives a good yield of pulp about equal to that obtained from Algerian esparto grass. After submitting to adequate processes, the grass may be considered suitable for the manufacture of pulp or paper (brown or white) either for local use or for export.

b) *Podocarpus spicatus* (Matai or Black Pine). — Not very satisfactory: — wide spread distribution in N. Zealand.

c) *Hibiscus tiliaceus* Linn. — Young stems consisting of fibrous bark enclosing soft wood, give a good pulp yield but of somewhat inferior quality in Fiji and suitable for local use only.

d) *Imperata arundinacea* Cyr. (3) (Lalang Grass). The sample received from Papua showed that this grass compares favourably with Algerian esparto grass, and is worth about the same price. For the manufacture of white paper, a slightly more drastic treatment than the latter is required, but unbleached pulp of good quality suitable for the production of strong wrapping paper and cardboard can however be prepared, and the grass used to advantage in Australia.

V. — *I. arundinacea* is also reported from the Federated Malay States, Ceylon and North Queensland.

---

(1) See *R.*, Feb. 1917, No. 149.

(2) Botanical identity to be ascertained by the Imperial Institute London.

(3) See *R.*, Feb. 1917, No. 149. (*Ed.*)

[498]

VI. — **Formosa.** — A successful paper making industry has been established, employing bagasse (1) (dry refuse of sugar cane after the juice has been expressed) as the raw material. Well made bagasse paper possesses several valuable qualities, it is far more durable and more waterproof than papers made from other materials. These are natural qualities and point to the conclusion that when advantageously employed it may be used for purposes beyond wrapping and printing

VI-VII. — **Madagascar.** — The following specimens are notified as giving advantageous results: —

a) *Ravenala madagascariensis*, common on territory lying between the forest area and the sea coast; 45 % utilisable cellulose, b) *Cyperus aequalis* "zozoro" and *C latifolius.* — Common in the marshes and peat districts · gives a good quality pulp: 22-23 % utilisable cellulose: c) *Phragmites communis,* "bararata, common in swampy districts in the west: d) *Hyphaene coriacea* "satrama" and *Borassus flabellifer* "dimaka" common in the savannah e) *Trema grisea* "andrarezina · f) *Dombeya* spp. "Lafatravonono" and "Lafotrofotsy" g) *Cusonia* sp. "vantoilana". h) *Terminalia Arjuna* Bedd., specimens were introduced into Madagascar in 1900 by Em. **Prudhomme**, then Director of Agriculture in this Colony. The plants came from the Indies and Ceylon.

The fruit of these trees has recently been sent to the Jardin Colonial, Nogent-sur-Marne and investigations have been made to ascertain the possible utilisation of the same for tanning hides. However, the percentage of tannin content was found to be very low (2.80 to 3.61 %), and **Lavergne**, assistant in the research department of the Jardin Colonial, considered it advantageous to test the possibilities in connection with paper manufacture.

According to the results obtained in the laboratory it was found that the yield of dry cellulose undiluted., after baking for 8 hours, under pressure of 6 kg. (155-160°C) was 29 %. This cellulose is fine, long and gives an excellent greyish pink paper without blemish and very strong The fruits of *T. Arjuna* should therefore serve a distinctly useful purpose as a first quality material for the manufacture of paper, provided that large quantities could be obtained at a cheap rate.

i) *T. polymorphus* (See S Africa).

VIII. — **British Columbia.** — According to the reports published in 1918 by the Commission of Conservation of Canada, the total amount of timber in the coast region of British Columbia of species suitable for the manufacture of pulp is over 92 billion ft. or approximately 132 million cords. (1 cord = 600 board ft.) Nearly two thirds of this is western hemlock (*Tsuga heterophylla*). A wood which seems to possess the necessary qualities of fibre which permit its use largely in place of spruce for the manufacture of newspaper pulp; of the rest, 58 % is Sitka spruce (*Picea sitchensis*) and 42 % balsam (*Abies grandis* and *A. amabilis*). The country is just awakening to the value of western hemlock. The growth of the pulp and paper industry in Brit. Columbia was very rapid in the last two years.

---

(1) See *R.*, July-Aug. 1920, No 799 (*Ed.*)

IX. — UNITED STATES. — In the wood waste from veneer factories in the United States Forest Products Laboratory a considerable variety of raw materials were found suitable for the manufacture of high grades of paper. Among the veneer woods with paper making possibilities are: red gum (*Liquidambar styraciflua* L.); yellow poplar (*Liriodendron tulipifera* L.), cotton wood (*Populus deltoidea* Marsh); birch (*Betula lenta* L.); tupelo (*Nyssa aquatica* Marsh.); basswood (*Tilia americana* L.); beech (*Fagus americana*, Sweet).

Other economic factors being favourable, a mill could profitably operate on a daily supply of veneer waste equivalent to 50 cords of ordinary pulpwood.

IV-X-XI. — UTILISATION OF BAMBOOS (1). — The high price of wood pulp has caused paper manufactures to search for new materials which could be used as a source for paper pulp, and the most promising of these is bamboo. These yield a pecto-ligno-cellulose, intermediate in character between the cellulose of esparto and that of coniferous wood: when crushed and boiled it can be converted into an excellent, easily bleachable pulp. The 4 chemical processes which have been applied to the production of bamboo pulp are described in detail (*viz.* the sulphite, soda, sulphate, and lime, processes.). Art. XI gives a brief survey of the general distribution of species throughout the world : 320 species belong to the monsoon region of Asia (15 out of the 30 genera + 136 spp. in India) 179 species (belonging to 8 genera) (*Chusquea* and *Arundinaria*) in S. America; 49 in Japan; about 30 in the Philippines; 8 in New Guinea; 3 in Queensland; 4 in New Caledonia; 2 in the Pacific Islands; about 24 in Africa; 5 in Madagascar; and none in Europe, though a considerable number have been planted for ornamental purposes.

Particulars are given especially from the point of view of their utilisation for paper making, and of the present position and prospects of the industry in certain countries :—

X. — *India*. — A considerable amount of progress has been made in perfecting processes of manufacture during the last few years, and also in searching for further suitable areas from which bamboos can be extracted, and a possible factory site at sufficiently low rates to make it a profitable concern. The idea of manufacturing paper pulp from the raw materials available from the forests of India, dates back nearly 60 years, though it is only lately that schemes have materialised to utilise the bamboos in factories. PEARSONS' object in his article is briefly to review pre-and post war conditions, and to bring the available information up to date.

The interest now manifested in starting this industry coincides with the period of flowering of the more common species of bamboo such as: *Melocanna bambusoides*, *Cephalostachyum pergracile*, *Bambusa polymorpha*, *Dendrocalamus longispathus*, and *Bambusa Tulda*.

---

(1) See *R.*, Oct.-Dec. 1919, No. 1144. (*Ed.*)

The importance of this point cannot be over estimated when it is taken into consideration that these species will probably not flower again for from 30 to 40 years. As conditions now stand, in areas where bamboos have recently flowered, the amount of raw material will be least, and the cost of extraction greatest during the first years of working whilst the yield will tend to increase and the price of extraction to fall with every successive year.

Considerable advance has been made in the process of preparing bamboo pulp. The author quotes the latest treatments in India, and also in Scotland. It was not until 1912 that it was discovered that by crushing bamboos between heavy rollers, and then chopping them into small pieces, both nodes and internodes could be utilised together.

Under the present conditions, the author does not definitely state what the ultimate cost of producing 1 ton of air-dried pulp would be, but taking into consideration the improvements in manufacture as against the higher cost of labour, chemicals, coal, etc., it is thought that bamboo soda pulp can still be produced well within Rs. 125 per ton.

After a general survey of the various bamboo areas both in Burma and India, the most favourable position for a factory site is considered to be at Badarpur in the Kata-khal Catchment area, as all the main rivers by which the bamboo forests are drained, converge on that point, and here also the Assam-Bengal Railway crosses the Borak river.

The possible out-turn depends on 3 factors namely: 1) The area of the forests from which bamboos can be exploited: 2) the density of the crop; 3) the estimate based on the figures obtained by taking sample plots; 4) the rotation of cutting. The most suitable Indian bamboos from the point of view of abundance and availability are: *Bambusa polymorpha*, (" kyathung "), *Cephalostachyum pergracile* (" tinwa ") *Bambusa arundinacea* (" dongi ") and *Melocanna bambusoides* (" muli "), all of which have been found to give high yields of pulp.

The average yield per acre is 23.5 tons. The area of forests from which bamboos can be exploited is 164 000 acres, and the sustained annual yield will therefore work out to 570 585 tons. This is a far greater yield than could possibly be required by any one paper mill, and hence the opportunities for opening up further factories.

Attention is drawn to the fact that both bamboo and Sabai or bhabar grass (*Ischaemum angustifolium*) are found in some cases in the same locality and as the latter has up till now been found to give a better quality paper pulp than any bamboo, this fact should not be overlooked in the choice of a factory site. Bamboo pulp is equal to if not better than imported sulphite spruce. *I. angustifolium* is obtained from the hill forests of the Hoshangabad, Chlindwara, Butul and Narsinghpur Divisions.

In the first mentioned Division, a pulp mill for this grass and bamboo is under contemplation. The respective value of the proposed sites elsewhere is discussed. Taking everything into account probably no country in the world seems to have more extensive natural and accessible areas occucupied by the larger and more valuable bamboos than Lower Burma. The area of bamboo forests has been stated to be over 24 000 000 acres with a possible output of at least 1 $^{3}/_{4}$ million tons of dry stems per annum. The next largest areas occur in Bombay, Madras, Assam, Mysore and the native State of Cochin.

Ceylon. — Bamboos occur in the southern lowlands and at a height of 4000 to 5000 ft. on the mountains in the interior. The small *Ochlandra stridula*, and *Bambusa arundinacea*, *B. vulgaris* and *B. nana* are cultivated and much used in building, but these could probably all be used as paper material. In the mountain region, slender shrubby species of *Oxytenanthera* (*O. Thwaitesii*) and *Teinostachyum* (*T. attenuatum*) and 5 spp. of *Arundinaria* occur.

Indo-China (1). — It has been estimated that there are 50 to 90 species of bamboo indigenous to French Indo-China, including several of those shown to be suitable for paper pulp in Burma.

China. — At least 60 kinds appear to occur in the country, including, *Phyllostachys heteroclada* "chung-chu," abundant in Central and Western China; *Bambusa arundinacea* "tzŭ-chu;" *Dendrocalamus giganteus* "nanchu" and the thinwooded *B. vulgaris* "Kwangin chu," commonly cultivated but less valuable as timber. These bamboo groves seem in most cases to be the result of deliberate cultivation.

Japan. — Although numerous species are indigenous, including no less than 17 species of *Arundinaria* and there are lands suited to bamboo throughout the country, the large quantities required for miscellaneous uses are mainly supplied from Formosa. *A. kurilensis* is the most northern known species.

Philippines (2). — 30 species. *Schizostachyum lumampao* ("caña bojo") treated by the soda process appear to be the most satisfactory paper material; an erect gregarious species sometimes 30 ft. high occupying considerable areas, averaging 9 000 canes per hectare, never cultivated.

Malaysia, Dutch east Indies — The common bamboo, *B. vulgaris* much cultivated in India, Mauritius, Cape Colony and Tropical America occurs both wild and cultivated from the plains to 3500 ft., in Java, Singapore, Celebes and the Moluccas. The spiny bamboo (*B. spinosa*) is abundant from Java to Borneo; the dwarf *B. nana* cultivated throughout the area, is half wild in Java and Singapore. Extensive forests composed almost entirely of *Gigantochloa maxima*, *G. ater*, and *G. aspera* occur, particularly at an altitude of 2000-4000 ft. *Dendrocalamus giganteus* which reaches a height of 120 ft. is also found and is very valuable; also *D. strictus*, *Dinochloa* spp. and *Schizostachyum* spp. which may prove as valuable as *S. lumampao* in the Philippines.

Tropical Australia. — No species seem to be abundant, 3 imperfectly known species have been described from the northern parts of the continent.

(2) See *R*, April 1921, No. 389. (*Ed.*)

[498]

Pacific Islands. — The chief species indigenous to the Islands of the Central Pacific, from Hawaii to Samoa and Fiji is *Schizostachyum glaucifolium* 9 ft. high, often cultivated but not occuring in a markedly gregorious manner when wild; not yet tested as a paper material.

Tropical America and W. Indies. — Most of the bamboos of America belong to genera peculiar to the new world, *Guadua* taking the place of *Bambusa*, and *Chusquea* that of *Schizostachyum*, etc., only *Arundinaria* and *Nastus* perhaps being indigenous to both hemispheres, although some Asiatic species have become naturalised in the W. Indies. Many years ago a considerable quantity of paper pulp was annually made from *Arundinaria macrosperma* (reed bamboo) in North and South Carolina and the lowlands of the Mississippi. The utilisation of this species by modern methods is now under consideration in Louisiana.

Amongst the species of *Arthrostylidium* growing at high altitudes may be mentioned *A. racemiflorum*, in Mexico, *A. Schomburgkii*, the longest of the known bamboos in Guiana, and in the mountains near the sources of the Orinoco and Rio Negro. *Chusquea aristata* occurs in the same region in dense thickets. *Guadua angustifolia* forms forests several leagues in extent in hot valleys and at moderate elevations (about 2400 ft.) in Ecuador and Colombia, but the species of this genus probably more often occur in comparatively small thickets. In Trinidad, a considerable portion of the area occupied by gregarious bamboos is made up of introduced Asiatic species, especially *Bambusa vulgaris*, although *Guadua latifolia* (Venezuelan sp.) also occurs, and at high altitudes the large *Arthyrostylidium excelsum* and *A. pubescens* are found. Paper has for some years been made more or less completely from bamboo pulp in Trinidad. In Jamaica and British Guiana, bamboos do not at present occupy extensive continuous areas although there are evident possibilites in store.

IV. — *Brazil.* — A bamboo from Brazil was received by the Imperial Institute under the name of " tabocca brava " for examination as a source of paper pulp. The material was analysed with the following results %: moisture 9.8, ash 3.3, cellulose (expressed on cane as received) 49.9, cellulose (expressed on dry cane) 55.3.

A good yield of pale coloured pulp was obtained furnishing fairly soft papers. This, however, could not be satisfactorily bleached, but as the pulp possessed good felting properties, by adopting the sulphate method it seems possible to obtain white paper.

Africa. — The cultivation of bamboos, especially of species of *Phyllostachys* from the Himalayas has been suggested for Morocco and the coast of Algeria to fix sand dunes and dry up marsh land. *Oxytenanthera abyssinica,* the most widely distributed African species ranges from lake Tsana in Abyssinia to Liberia, Angola and Nyasaland, occurring at altitudes where snow is frequent. In W. Africa, with the exception of some small herbaceous species described from the Cameroons, bamboos are only represented by introduced Indian forms which are grown to a considerable extent on the Gambia. *Arundinaria alpina* occurs in the Kenya forests of E. Africa, and in Portuguese E. Africa. In S. Africa these are replaced by *A. tessellata*.

VII-XI. — *Madagascar*. — Several species of *Bambusa* have been successfully introduced in recent years and have been tested at Grenoble, France, and found to yield a satisfactory paper pulp. The following indigenous species are prevalent: — *Beesha capitata*, *Nastus* spp., *Cephalostachyum* spp. and *Schizostachyum* spp.

Conclusions: — The experiments so far made have clearly proved that a high class paper can be produced from bamboo pulp. On the whole it is too good for the manufacture of ordinary news-print, and is more suitable for better grades of printing paper. The cultivation of bamboo for paper pulp offers a number of advantages over spruce and other pulp woods. As bamboo culms are available for extraction within 8 or 10 years from the time of sowing, and if a proper system of rotation cutting is adopted, their cutting can be continued for a period of 30 years or more, that is until they flower. Propagation by seed and cuttings of half matured culms is relatively simple The latter are about 3 ft. long and should include, if possible part of the rhizome. They may be inserted vertically, with the 2 lowest nodes buried, or horizontally in prepared beds.

The occurrence of various native or introduced bamboos at various altitudes in many countries is sufficient to show that,, where they do not already exist in large enough quantities to be exploitable for paper pulp, there would be no difficulty in introducing and cultivating those species which have been proved suitable for this purpose

In connection with plants suitable for the manufacture of cellulose and paper, attention is drawn to the following interesting publication: — *Précis historique descriptif, analytique et photomicrographique des végétaux propres à la fabrication de la cellulose et du papier* (50 pl.), by MM. Léon ROSTAING, Marcel ROSTAING and FLEURY PERCIE DU SERT. H. Dunod & E. Pinat, Paris.

499 – **The Seeds of *Prunus brigantiaca* Vill. and their Oil.** — RAVAJOLI, L., in the *Bollettino dell'Associazione Italiana Pro Piante medicinali, aromatiche ed altre utili*, Year IV, No. 3, pp 38-41. Milan, March 1921.

The "*prunier des Alpes*" or "*marmotier*" (*Prunus brigantiaca Vill.* = *Armeniaca brigantiaca* Pers.), is a shrub growing wild in some parts of Dauphiné, especially in the neighbourhood of Briançon (hence its name of *brigantiaca*) and in the Piedmontese Alps. From the kernels of the fruits an oil is extracted, which is called "huile de marmotte," and is nearly all consumed locally. Cakes made of it are sometimes fed in small quantities to stock, but much care must be taken not to give more than a limited amount, as it contains hydrocyanic acid, and may easily prove poisonous.

A hundred grammes of the fruits contain about 145 stones (average weight 0.69 gm) 32 % of which are kernel and 68 % shell; the latter forms an excellent fuel, burning easily with the formation of but little ash (0.42 %).

The chemical composition of the kernels is as follows: —

	Per cent.
Water (at 100-105° C)	7.60
Ash	2.44
Crude protein	23.12
Crude fats	48.01
Crude fibre.	3.51
Nitrogen-free extract.	15.32

The ash of the kernels is very rich in phosphoric anhydride (35.57 % of ash = 0.87 % of kernels) and in potash; it gives a rather strong reaction of sulphuric acid, lime, and magnesia, and contains small quantities of iron oxide and traces of chlorine.

The kernels contain a small amount of organic phosphorous in the form of lecithin and lecithides; the content of the lecithin was: —

Free lecithin	16 per cent
Combined lecithin (lecithides)	0.21 per cent

The kernels contain 0.123 % of total hydrocyanic acid, and 0.048 % of preformed hydrocyanic acid. The combined hydrocyanic acid corresponds to 1.25 % of amygdalin.

The kernels also contain reducing sugars which calculated as glucose, amount to 4.3 %, and a few grains of starch; but their chief costituent is oil which amounts to 48 %.

By pressing as much as 35 to 40 % is obtained, it is of a light yellow colour and slightly bitter, with a strong smell of bitter almonds; its constants are as follows: —

Specific gravity at 15° C		0.9178
Refractive index (ZEISS-WOLLNY oleorefractometer)		64.5°
Thermic degree	TORTELLI thermometer	47° C
	JEAN	38° C
Freezeing point		19° C
Solidification point of fatty acids		7° C
Melting point of fatty acids		16° C
Refractive index of fatty acids		51°
Refractive index of acety lated fatty acids at 25 C		53°
Saponification index		194.9
Ester index		190.3
Acid Index		4.6
Index of free volatile fattyacids		0.5
Iodine index		89.4°
Acetyl saponification index (BENEDIKTS' metod)		218.8
Acetyl index		123.4
Acetyl acid index		95.4

"Marmotte" oil is consumed locally either pure or mixed with olive oil.

500 – **The Cultivation of *Fraxinus chinensis* in China.** — NOGARA, L., in *L'Apicoltore moderno*, Vol. 12, Nos. 1-2, pp. 3-8, 6 fig. Turin, January-February, 1921.

In compliance with the request of the *Apicoltore moderno*, the author, who is a member of the Institute of Foreign missions at Milan, sent from Lou-y-Lien Ho-nan, China, the following information accompanied by photographs.

The tree furnishing the wax is *Fraxinus chinensis* Roxb = *F. xanthoxyloides* Wall. It is planted in rows and allowed to grow to the height of 1 metre. Then it is cut down level with the ground every 2 or 3 years, and permitted to send up fresh shoots. Branches of 2 or 3 years of age no longer produce wax.

At the beginning of May, or a little later, are attached the eggs of *Coccus chinensis* West, which were collected the previous winter from *Fraxinus chinensis.* A small straw bag containing a dozen eggs is tied in the centre of the young tree which is all bandaged up. Two or three days after, the scale insect hatches out; it bites the branches in different places, and dies at the end of a fortnight. As a result of these slight lesions, a sort of white, odourless efflorescence 3 to 4 cm. thick exudes, which covers each branch extending from the point of its attachment to the trunk, to a height of 30 cm. In September, the lower part of the tree is completely white. The wax is then collected (it falls from the tree at a touch), and purified by being melted in boiling water, and then passed through a bag.

This plant-wax is used in a variety of ways; it is applied for staunching wounds, and is one of the ingredients of the mixtures employed in the manufacture of candles, to which it imparts greater consistency. The author by adding a little of this plant-wax to bees-wax, was able to make beatiful white candles, that did not bend even in great heat- (40°C.) and burnt slowly without guttering. This chinese ash grows in many places, but it does not produce wax everywhere. The product is very white in some districts, but in others it is always yellowish in colour.

Coccus chinensis is very common in some regions; in others it is rare, and only supplies local requirements. Before the war Chinese plantwax sold at 1 Chinese dollar (2 s. 1d. at par) per Chinese catty (1.50 lb.) now, its price is twice as much.

501 – **Sources of Turpentine and Resin: In India, *Boswellia errata*; In South America, *Cercidium spinosum*; In Australia, *Xanthorrhoea. spp.*** — I. A New Source of Turpentine and Resin in India, Commercial Importance of *Boswellia serrata* gum resin, *Bulletin of the Imperial Institure*, Vol. XVII, No. 2, pp. 159-177. London, 1919. — II. A New Resin from S. America *Ibid*, Vol. XVII, No. 3, pp. 296-297, — III. The Composition and Uses of Australian *Xanthorrhoea* Resin. *Ibid.* Vol. XVIII, No. 2, pp. 155-62, 1920.

I. — *Boswellia serrata* Roxb. — A summary of the information given by R. S. PEARSON and PURAN SINGH (*Indian Forest Records*, 1918, 6, p. 303) concerning the methods of tapping the trees, the preparation of the turpentine, rosin and gum, their chemistry, commercial value and industrial uses This investigation has shown that *B. serrata* gum-resin, which has hitherto been employed in India to a small extent chiefly as a substitute for *B. Carteri*, and *B. Frereana* in the preparation of incense, is capable of furnishing products of considerable commercial importance, and it seems probable that their preparation will constitute a profitable industry.

As a general rule old trees with black bark, dwarfed and suppressed trees, and trees with a short boll, yielded no gum-resin, and this was the case also with a large number of healthy trees of small girth. On the other hand, all sound and vigorous trees of 30 in. girth and over, all trees attacked by borers, or otherwise diseased, and generally all hollow trees, yielded well.

The average yield of gum resin per tree is as follows:

Girth of tree	Average yield
24-30 in.	0 9
30-36 in.	1 3
36 in. and over	1.9

In the Nimar Division, Central Provinces, 1023 trees tapped from January 21 to February 23, confirmed this statement.

The following conclusions as to the best methods of tapping were drawn from the results of experiments conducted in various localities :—

a) The method of tapping should consist in shaving off a thin band of bark about 6 in. broad, 2 ft. to 2 ft. 6 in. from the base of the tree,

b) tapping should be commenced in November and should stop before the break of the monsoon;

c) "freshing" should be undertaken every 4th or 5th day, and should consist in removing a thin shaving of ½ in. to 1 in. of new bark from the upper edge of the original belt, and carrying down the "freshing" to within 1 in. of the lower edge.

d) tapping of trees below 30 in. in girth is not advocated.

From the results of analyses of 8 samples collected at Khandesh during 1917, the average composition of the gum resin may be taken to be as follows: % moisture 10-11; turpentine oil 8-9, resin 55-57, gum 20-23, and insoluble matter 4-5.

II. — *Cercidium spinosum*. Tulasne.. — This small three related to the Caesalpinias grows abundantly in certain parts of the Goajira Peninsula, Colombia, and it is stated that the resin forms a layer on the trunk and branches of the tree, and that the roots, when exposed to the air, also become covered with resin.

The sample received at the Imperial Institute consisted of coarsely ground, translucent, yellow resin, containing brown particles of bark, and on examination gave the following analytical results:

Specific gravity at 17°/17° *C*	1.079
Moisture	1.3 %
Matter soluble in water	0.6
Matter soluble in hot alcohol	90.6 *
Ash	3.0

* The remaining 9.4 % insoluble in hot alcohol, consisted chiefly of bark.

The resin contained no volatile oil. The following results were obtained on examining the purified resin: melting point 77°C; acid value (mg. of potash per 1 gram of resin). 23.8; saponification value (ditto) 84.1, iodine value 85.8 %.

A varnish made of 1 part of purified resin to 1 part of turpentine gave a clear, pale straw coloured coat, but dried very slowly, the surface still being sticky at the at the end of 14 days. The general opinion was that the resin would not be suitable for the preparation of spirit, turpentine or oil varnishes.

III. — *Xanthorrhoea* spp. — The chief species yielding resins are: 1) *X. hastilis* R. Br. of Eastern and South Eastern Australia which yields a yellow resin known commercially as yellow gum acaroid, Botany Bay gum, yellow yacca gum etc,, 2) *X. arborea* R. Br. of Queensland and New South Wales. 3) *X. australis* R. Br. of New South Wales, Victoria and Tasmania 4) *X. Tateana*, F. Muell., of S. Australia 5) *X. Preissii* Endl. of S. W. Australia., all of which yield a red resin known as red gum acaroid, red yacca gum, black boy gum, etc.

The resins have been used to some extent in the past for making varnish, sealing wax, etc; and it was demonstrated many years ago that the resin could be used as a source of picric acid. A large number of experiments have been carried out with regard to the preparation of picric acid from both red and yellow resins and the possibility of using them as substitutes for shellac and rosin in the manufacture of lacquer for metals, of spirit varnish for wood,a nd of sealing wax; dyeing trials with these resins have also been carried out.

The results of preliminary experiments indicate that the yellow resin should yield at least 30 % picric acid, and the red resin at least 25 %, though on the commercial scale higher yields could probably be obtained.

Lacquers prepared from *Xanthorrhoca* resin appeared to stand exposure in dry atmosphere satisfactorily, but deteriorated rapidly on immersion in water. A 30 % solution of red resin in methylated spirit gave a fairly lustrous but dark coat on sized wood. The use of these resins for the preparation of lacquer or varnish is somewhat limited by the fact that it is insoluble or only partially soluble in turpentine, fatty oils, benzene or petroleum spirit, although soluble in alcohol The varnish showed however, better resistance to wear than rosin (colophony) varnish, although somewhat inferior to shellac in this respect.

It appears that ordinary red and yellow *Xanthorrhoea* resins could not compete in the United Kingdom with fustic or with artificial yellow or brown dyes.

The products obtained by the action of nitric acid on the resin under different conditions were picric acid, *P*-nitro-phenol, an amorphous nitro-compound and oxalic acid. The following products were obtained as the result of the action of oxidising agents on the resin:

a) Potassium permanganate: — oxalic acid about 40 %, acetic acid, small amount, carbonic acid, appreciable amount, vanillin about 0.2%.

b) potassium dichromate and chromic acid: principally an insoluble chromium compound.

An analysis of both kinds of resins gave the following resuls:

		Yellow	Red
Moisture (in vacuo at ordinary temperature)	%	3.0	3.5
Ash	%	1.3*	.24
Matter insoluble in alcohol (chiefly woody matter) ..	%	13-14	4
Matter insoluble in ether	%	23	16
Melting point (determined on the powdered resin in a capillary tube)..	%	97° C	110° C

* Including some sand.

502 – **The Economic Aspects of Cinnamon Cultivation in India and the Gold Coast.** — I. MENON, C. K. (Forest Ranger, North Mangalore Division, Economic Aspects of Cultivation in South Kantara in *The Indian Forester*, Vol. XLVII, No. 2, pp. 77-81. Allahabad, Feb., 1921. — I. Cinnamon Bark from the Gold Coast. — *Bulletin of the Imperial Institute*, Vol. XVI, No. 2, pp. 146-147. London, 1918. — III Further Investigations on the Value of Cinnamon Bark from the Gold Coast. — *Ibid.* Vol. XVII, No. 2, 1919.

I. — In the coast district of South Kantara, Cinnamon (*Cinnamomum Zeylanicum*) grows abundantly at elevations varying from 100 to 700 ft., and up to 3500 ft on the Ghat slopes. It thrives on any kind of soil except that in which sand predominates, and can stand any amount of rainfall. It flowers in January, the fruit ripens in May, and every few years bears a heavy seed crop.

The propagation of this species can be taken in hand without much difficulty as extensive areas in the Government unreserved forests which now contain only poor growth, can be brought under cinnamon cultivation by dibbling in seeds of the bitter and pungent varieties or by broadcast sowing. Cinnamon growth could thus be concentrated within small and compact areas, and instead of auctioning the same areas annually, the district sold during one year would be resold only after 3 years. A sustained yield of leaves for oil extraction, bark and fruits can thus be maintained.

The medicinal use of cinnamon is now being recognised, especially, with regard to cholera.

The author states that now that the formation of utilisation circles is under contemplation and at least one province, *viz.*, the UnitedProvinces has taken the lead, it is expected that others will follow this example, and it is hoped that this industry will claim the attention of experts in the area under discussion.

II. III. — An analysis of samples of cinnamon bark sent to the Imperial Institute, coming from (*a*) Tarquah, (*b*) Assuantsi (*c*) Coomassie, Aburi, on the Gold Coast.

It was ascertained that the entire oil (heavy and light fractions included) which would be obtained on distilling on a large scale should contain at least 68 % of aldehydes. The small scale distillation trial made with the bark in order to determine the yield of volatile oil, gave the following results:

	Samples			
	Tarquat %	Assuantsi %	Coomassie %	Aburi %
Heavy oil	1.18	1.5	1.6	1.4
Light oil	0.3	0.3	0.4	0.3

All four samples of heavy oil had a very fragrant aroma and closely resembled each other in this respect.

As a result of a chemical examination it was evident that all these barks furnish high yield of oil which contains a large percentage of cinnamic aldehyde. In both these respects the barks are superior to Ceylon cinnamon bark.

503 - **The Cultivation and Use of Buchu *Barosma betulina* in South Africa** — COMPTON R. H., and MATHEWS, J. W. (National Botanic Gardens Kirstenbosch), in *Journal of the Department of Agriculture, Union of South Africa*, Vol. II, No. 3 pp. 223-228, figs 3, Pretoria, March, 1921.

Owing to the increased interest taken in the cultivation of *Barosma betulina*, it was thought desirable to publish the conditions under which such satisfactory results have been obtained at Kirstenbosch, with conclusions drawn from observations thereon. The future prospects of buchu as a field crop are bright as the demand for the herb and oil is increasing rapidly throughout the world. Under distillation buchu yields a resin and also a volatile oil, and according to the analysis made by THOMPSON the followed are the yields for the three commercial varieties, calculated as percentages of the weight of dried leaves: —

	Resin	Oil
B. betulina	4.25	1.45
B. crenulata	3.75	1.6
B. serratifolia	3.45	1.0

The oil can be obtained from green leaves as well as from the dried herb, and it has been estimated that the yield of oil from green *B. betulina* leaves is about 1 %, and the green twigs give a yield of about 0.5 %. As the herb loses about half its weight in drying, it is clear that a considerable waste of oil takes place in this process. The most economical way of extracting oil, therefore, would be by distillation of the green shoots shortly before cutting. The oil derived from *B. betulina* leaves is a clear-yellowish mobile liquid, which deposits a mass of colourless needle crystals of diosphenol or " Barosma camphor " when it is cold. The oil from the twigs is inferior, no diosphenol crystallising out on freezing. The oil from *B. crenulata* leaves is also deficient in diosphenol. The volatile oil, taken internally has a marked effect on the mucous membrane and is therefore employed in the treatment of various diseases.

At Kirstenbosch " dry " cultivation is practised and is generally the most suitable for the western and south-western districts. Deep trenching is essential to encourage drought resistance and the longevity of the plantation. The soil there is a deep red sandy loam, rather adhesive when wet, and caking somewhat on drying; the subsoil is a reddish clay with occasional seams of iron-stone and quartz gravel. The authors consider that good peach, apricot, vine or hillside lands would suit buchu well.

Sowings should be made in drills 1 inch deep and 3 ft. between the lines, seeds 2 or 3 in. apart. Germination takes place in about a month but is invariably poor, the average being from 40 to 50 %. About 7 lb. of seed are required per acre. Propagation by cuttings is being tried this season.

At a year old the plants can be cut back to 3 in. from the ground to induce a bushy habit, and at 2 years cut back again from 1 to 2 in. above previous year's cut, and so on annually, the resulting bush slowly increasing in surface area and yielding a maximum of leafy twigs.

The best time for harvesting is March or April, as soon as a rain has washed the foliage clean, and buchu should not be collected by breaking off the branches as has often been done and which causes injury or death of the plant. Drying should be done as quickly as possible, and to keep a good colour it is essential that this should be done in the shade. A corrugated roof, with open sides, or latticed with spars or leafless branches would approach the ideal. The dried buchu should be as green as possible to avoid loss of oil content. For export purposes the buchu should not contain more than 10 % of the small green twigs and none of the larger ones.

To secure a crop of seed from cut-backs, it is necessary to allow the bushes to develop unchecked and uncut for 2 or 3 years.

The National Botanic Gardens will be pleased to identify any specimens sent of the varieties of buchu occurring wild; correspondents in the Union can send specimens of seeds free by post or rail if addressed O. H. M. S. to the Director. Seed is distributed from this centre on application may be available, preference being given to Members and Associates of the Botanical Society of South Africa.

504 – **Cultivation and Manufacture of Tobacco in Mauritius.** — *Bulletin of the Imperial Institute*, Vol. XVIII, No 2, pp. 252-256 London, April-June, 1920

The results of experiments conducted in 1916-17 with Réunion tobacco in Pamplemousses Botanic Garden, and in two other localities in the island have already been reported (1) In the 1917-18 season, 3 acres were planted at Pamplemousses, 3 acres at Riche Terre and ½ acre at La Ferme.

These trials have indicated that the " tabac bleu " is more resistant to disease than types of Virginia, Sumatra and Turkish Tobaccos tested previously, although to a certain extent subject to attack. It is estimated that 100 plants will yield about 5 kg. of seed. Tobacco plants of the Réunion type appear to be particularly sensitive to water, and provided that the rainfall is fairly evenly distributed throughout the year, irrigation is not necessary. In general, the best months for planting in Mauritius are apparently December to February. The plants are mature about 4 months after being planted out in the field, and after being cut off within

---

(1) See *R.*, September 1918, No 993 (*Ed*)

3 or 4 in. of the ground, a crop of ratoons may be allowed to arise from the stumps; but their production rarely exceeds 1/8 of that of the original plants, and it seems probable that if ratooning is practised it will not be profitable to harvest more than one ratoon crop.

The yield of green leaf varies greatly with local conditions but may be said to average 3 ½ to 4 tons per acre.

The yield of cured carotted tobacco (a carotte consists of a torpedo shaped bundle 18 to 22 lb. in weight, covered with a wrapping of dry banana leaves, known as "empondres" and tightly bound round with sisal cord.). amounts to about 10 % of the weight of the green leaf, and the manufactured tobacco to about 34 % of that of the first mentioned type or 3.4 % of the weight of the green leaf.

505 – **The Process of Ripening in the Tomato, Considered Especially from the Commercial Standpoint in Florida U. S.** — SANDO C. E., in *United States Department of Agriculture, Bulletin* No. 859, pp. 1-38, pl. 4, tables 10, figs 3, bibliogr., of 58 works, Washington D. C., Sept., 7, 1920.

With the object of discovering the chemical basis for the inferiority of commercially picked and ripened Florida tomatoes marketed in the north during winter and spring, a series of analyses were made of tomatoes of several degrees of maturity, and of others ripened artificially under various conditions of ventilation. The fruit employed was obtained from plants of the Livingstone Globe variety grown at Peters, Dade County (Fla)., which is almost exclusively used for winter shipping to northern markets. These plants were set out in January, and had the same treatment as the commercial plantings.

It was found that the only way to secure samples of comparable maturity for analysis was to tag the blossoms and pick the fruit at a definite age, as maturity is dependent upon age and not size, and ripening proceeds at a uniform rate.

The analyses indicate that in general throughout the ripening period there is an increase in moisture, acids and sugars, and a decrease in solids, total nitrogen, starch, pentosans, crude fibre, and ash. The most striking change is that undergone by carbohydrates. In the first stage it was noticed particularly that insoluble carbohydrates composed 52.1 % of the total carbohydrates present, while in the last stage, that of ripe fruit, soluble carbohydrates were in excess, amounting to 77.3 % of the total. Nearly all the total sugar is apparently invert sugar and this increases from 25.56 % in the case of 14-day old fruit to 48.32 % in ripe fruit. Starch decreases during maturation from 15.84 % to 2.65 %. The most marked decrease takes place during the period of transition from green to red. Pentosans decrease, but only to a comparatively slight extent. Total nitrogen decreases gradually during ripening, and the correlation between this and total carbohydrates holds good with respect to other fruit as well as to the other parts of the plant (excluding the lower leaves).

The percentage composition of fruit picked green but ripened with free access of air and light differs only slightly in composition from naturally ripened normal fruit, and contain more sugar-free solids, slightly more acid, and less sugar than the latter.

The effect of lack of ventilation on ripening is to increase the acid content approximately 138 % over that of normal fruit. The flavour of tomatoes ripened without ventilation is very inferior. The soluble carbohydrate content showed a decrease of nearly 21 %. Commercially ripened green fruit, wrapped with one layer of paper, shows an increase in acid of approximately 102 % and a sugar decrease of nearly 5 % compared with corresponding tests of normally ripened fruit. The results of wrapping with 3 papers are less marked, the acid increase being only about 58 %.

The data presented also indicate the fact that green tomatoes ripened when exposed to air and unwrapped are superior in taste and chemical composition to the same fruit ripened when wrapped in paper. The combined results of picking fruit green, of wrapping, and of closing the cars in transit probably account for the total differences existing in quality between commercially shipped and normally ripened tomatoes.

506 - **Fruit Cultivation at High Altidudes in Colorado U. S.** — McGinty, R. A., in *Colorado Agricultural Experiment Station Bulletin No.* 256, pp. 1-19, figs. 8, Fort Collins, Col., 1920. (Abstract in *Experiment Station Record*, Vol. 44, No. 3, pp. 234-235. Washington, 1921.)

A progress report on experiments with orchard and small fruits and vegetables that have been conducted at the Fort Lewis School of Agriculture a branch of the State Agricultural College, since the spring of 1916, The work is being conducted primarily to secure information relative to varieties and cultural practices suited for the short growing season in the high altitudes of Colorado. The altitude at the school is slightly more than 7 600 ft., and frosts occur as late as June 10 and as early as September 1.

No definite conclusions are drawn from the orchard work thus far, as the trees, which consist of several varieties of apples, crab apples, plums, and sour cherries, have not come into bearing, with the exception of a few fruits on some of the plums and cherries. Indications are that the chief trouble will be blossom destruction by late spring frosts. Rabbits also cause serious trouble by eating the bark on scaffold limbs during the prevalence of deep snows. The trees themselves are apparently as hardy as elsewhere in Colorado.

The work with small fruits has been handicapped by poor planting material. Thus far, however it appears that strawberries should succeed if well mulched with straw in the fall. Raspberries give promise of some success if the canes are covered with earth in the fall. They are apt to suffer from late spring frosts, and the cover should be gradually removed in early spring in order to harden the young growth, and also to prevent the development of spindling shoots under the earth cover during a warm spell of weather. Gooseberries and currants appear to be well suited for cultivation in high altitudes on account of their hardiness and late blooming habits.

507 - Cultivation of Date, Pomegranate, Crab Apple, Guava, and *Grewia Asiatica* as Practised near Shikarpur, Sind, India. — BARAKZAI, M. U. F. (Agricultural Department, Sind, in *Department of Agriculture, Bombay, Bulletin*, No, 98, pp. 1-14. Bombay, 1920.

Shikarpur is a famous centre for fruit-growing and contains about 150 orchards covering an area of 868 acres. This area is divided among the different fruits as follows (acres): date palms 230 — mangoes 167 — pomegranates 139 — oranges and lemons, 135 — *Grewia asiatica*, 91, miscellaneous (peaches, apples, guavas, jujubes (" ber ") 106. The author confines his attention in this case to the cultural details concerning the less well known species: —

I. — EDIBLE DATE. (*Phoenix dactylitera*). — Attention is drawn to the fact that sandy loam is probably the best medium for successful cultivation of the date palm, although it is not uncommon to find it flourishing in heavy clay and even in salt soils. Transplanting suckers is the most advisable method of propagation. Sowing seed is not practised, as most of the seedlings thus obtained appear to be males, and the few females that remain do not possess the characteristics of the parent.

In the first 3 years after transplanting, irrigation is necessitated. During the first quarter. — April-June, well water is applied every alternate day in order that the seedlings may strike root. From July onwards, weekly applications are sufficient.

Direct manurial or intercultural treatment is not adopted, nor is it advisable, but the intermediate spaces are ploughed and manured to grow vegetable crops, seedlings of fruit etc. A yard round each palm the earth is well beaten and a mound raised to enable the plant to withstand high winds.

The eighth year is considered to be the average year from which an appreciable quantity of fruit should be obtained. Each palm produces from 10 to 30 fruit stalks; in better varieties, 10 spathes only are allowed to fruit, the rest being cut off to support the development of the remaining fruit to their maximum capacity. (Each bunch yield from 10 to 40 lb. of dates. The total yield per plant ranges between 100 to 400 lb.). The fruit season lasts from May 15 to October 15. The fruit appears in the market in 3 shapes 1) unripe and acid " khasoon " (made edible by keeping them in closed earthem jars in a hot room for a night) 2) secondary stage sold as " doka " (80 lb. of doka to which ½ lb. common salt and 3 lb. water are added in earthem jars, for about 2 hours in the evening then placed in a close room for a night, are converted into the soft, sweet dates " luni-kharkun); 3) ripened on the tree " van pakyun ".

Parrots, sparrow and crows are common bird pests. No fungus or insect disease is known to occur in the locality of Shikarpur.

All parts of this palm except the roots are used for industrial purposes: leaflets for fans, matting, brooms and baskets; whole leaves for well ropes; dried fruit stalks for brooms and bird cages; fibrous material for ropes and stuffing for pack saddles, etc.

II. — POMEGRANATE " Anar " (*Punica Granatum* L.). — Eighteen months after making and planting cuttings the land selected for the plantation is irrigated, ploughed twice, levelled and laid out in small plots $1\frac{1}{4}$ to $1\frac{1}{2}$ acres in size. Parallel furrows 12 × 18 in. are made 12 ft. apart. Along each channel and on one side only, circular holes are dug; these are left exposed for about 10 days, the excavated earth mixed with 50 lb. cattle manure, and turned into the pits. Irrigation is given about twice a week at the start, but when farily established water is applied once a week thoughout the year (interval shortened if white ants are troublesome). Along the borders of the channels are sown *Momordica Charantia, Luffa acutangula, Hibiscus esculentus.* Other crops sown in the plantation are chillies, *Rumex acetosa, Trigonella Foenum-graecum* etc.

These crops are only cultivated during the first three years, when the pomegranates begin to yield. At this time also, weeding is stopped and the growth of natural grasses is encouraged as these provide an excellent green feed for cattle. The following weeds are found on these plantations, all serving as use ful feeds : — *Eragrostis cynosuroides, Eleusine flagellifera, Cynodon Dactylon, Panicum colonum, Cyperus rotundus, Digera arvensis,* and *Andropogon annulatus.*

From 5 to 50 years, maximum yields are obtained. The average number of 'Anars' borne by each plant is 70, each of which weighs from $\frac{1}{2}$ to $^3/_4$ lb. In the locality in question, 12 varieties (6 sweet pulped and 6 acid) are commonly grown, and all command a ready sale. Apart from the use of the fresh fruit, the syrup is used as a febrifuge; dried rind and flowers in wool colouring; unripe flowers dried and pounded to make snuff; green leaves as a medicinal paste-bark in several medicinal preparations.

III. — CRAB APPLE "Soof" (*Pyrus malus* L.). — This differs from the well-known variety in other countries in the fact that it is neither so big nor so sweet flavoured. This fruit appears to have a short life extening over 20 years or so; the yield of ripe fruit ranges from 20 to 60 lb. per tree, with an average of 30 lb. per plant.

IV. — GUAVA "Zetoon" (*Psidium Guava* L.). — A fully ripe fruit picked from the tree and crushed to squeeze out the seeds. These are then mixed with dry rotten but powdered cowdung, and sown in a 10 ft. square nursery bed, usually in March or August. Germination occurs within about a month. Irrigation is given every 5 days. The same methods of cultivation are employed as for the pomegranate, and also the catch crops are identical. The hollow made opposite to each plant along the other border of the furrow is dug $\frac{1}{2}$ ft. deep and 20 lb. farmyard manure applied, in February or March.

Each plant yields on an average 30 to 40 lb. of fruit : 60 lb. being the maximum yield. There are 3 varieties usually growing in the gardens: 1) Khasi (seedless), 2) Vanga · (elongate); 3) Gedi (small fruited).

The fruit is the only useful marketable product of the plant.

V. — "PHARWAN" (*Grewia Asiatica*). — A small but very productive perenennial shrub. Ripe berries, collected during May are mixed with fresh moist cowdung and kept in a jar for 2 days, then sprinkled on small ridges 9 to 12 in., apart. Irrigation is necessary every alternate day. The seedling are transplanted after 3 years, after preparing the land as described for pomegranate. After transplanting (March-April), irrigation is given at an interval of 3 days during the summer and of 6 days later on and none during the winter. All shoots of full grown plants are annually pruned down to the stump in January. The plants fruit 5 years after sowing, and each plant yields from 20 to 25 lb. ripe berries.

The berries provide a useful fruit during the hot weather, and the leaves and branches are also used for various local purposes.

508 - **New Variety of Prune Suitable for Growing in the South-Eastern United States.**— See No 486 of this *Review*.

509 - **Some Facts and Figures Regarding Banana Cultivation in India.** — BURNS, W., (Economic Botanist, Bombay) and DANI, P. G., (Bombay Agricultural Department) in the *Agricultural Journal of India*, Vol XV, Pt. IV, pp 386-392. Calcutta, July, 1920.

Records of two plantations in the Ganeshkhind Botanical Garden The two varieties used were: 1) "Soni" (local name) with a medium sized very sweet, yellow skinned fruit and 2) "Rajeli" ("Rajapuri" or "Gujarathi"), more dwarf in habit and with a more angular and slightly coarserfruit.

The yield of raw fruit for the plantations was as follows:

Variety	Date	Weight per acre	Number of fruits per acre
I Soni	June 1915 — March 1919	27194 lb	140984 lb.
II. Rajeli	June 1916 — March 1919	23085 »	86050 »

The average yield per sucker (mother or daughter) during the period of Experiment I was 31.65 lb. in weight or 164 fruits in number, and the average number of days required was 1 year, 3 months and 7 days from the date of planting to the date of fruiting. From the date of harvest of the mother to that of the next generation the interval was 280 days. The yield in the 1st generation was more by an average of 72 fruits than that of the mother, and still more by an average of 3 in the 2nd generation than in the 1st (here the average of the three stools is taken).

In Experiment II, the average yield per sucker was 21.27 lb. or 79 30 fruits and the date of planting to the date of fruiting covered 1 year and 45 days, with intervals of 244 days from mother to 1st generation and 119 from 1st to 2nd generation. There was an average increase of 46 fruits in the 1st sucker generation and an average decrease of 44 fruits in the 2nd generation.

A manurial experiment was carried out, one part treated with a mixture recommended by Dr MANN and the other receiving local treatment. The results have been recorded in the *Annual Report of the Ganeshkhind Botanical Garden for the years* 1915-16, 1916-17, and 1917-18 and in *Bulletin No.* 89 *of the Bombay Agricultural Department.*

The following calculations show the probable profits from the cultivation of the "Soni" variety in the Poona District.

Cost of Cultivation.

Cost of labour, man charged at rate of 8 as per day
woman, child " " " 4 " " " "
and bullock.

Farmyard manure at Rs 2. per cart and poudrette at Rs. 2-4-0 per cart.
Two cart loads are equal to 1 ton (2.240 lb).
One basket is " " 20 lb.
56 baskets 1 cart load.

(The whole time of the existence of the plantation is taken as three years and six months).

The following are calculated per acre.

EXPENDITURE

	Rs.	A.	P.
(1) Two ploughings crosswise by an iron plough CT2 or Arlington, two pairs and two men for 4 days	8	0	0
(2) Disking and harrowing, one pair and one man for the whole day . . .	1	8	0
(3) Digging pits; size 2 x 2 x 2 1/2. Pits required for an acre 15 feet apart are 193. One man digs 5 pits in one day, 39 men finish the work in one day	19	8	0
(4) Suckers required 200, at the rate of Rs. 10 per 100	20	0	0
(5) Manuring at the time of planting, F. Y. M. 80 lb. per plant (14 cart-loads required)	28	0	0
(6) Carting manure at R. 1 per cart.	14	0	0
(7) Planting suckers; one man plants about 25 suckers in one day . . .	4	0	0
(8) Harrowing and levelling after planting.	1	0	0
(9) Preparation of beds and water channels, one man prepares about 16 beds of the size required per day	6	0	0
(10) Irrigation charges: water generally given for 10 months in a year excepting rainy season; 30 waterings in all for one year. Irrigation Department charges per acre Rs. 22-6-0 for crop like plantain (G. R. N° 6371, dated 27th June, 1917), for three and half years	78	12	0
(11) Watering charges; in all 105 waterings for the whole time of the plantation; one man can irrigate one acre in a day	52	8	0
(12) Stirring, digging and weeding the beds once every three months 12 men can finish it in one day. 14 such operations	84	0	0
(13) Manuring: Generally manured every six months. For the method of manuring as described, the total cost comes to	173	10	0
(14) Land assessment to Government for three years at the rate of Rs. 4 per acre.	12	0	0
(15) Rent of land on lease for three and half years at the rate of Rs. 20 per acre..	70	0	0
(16) Harvesting charges; per bunch 3 pies, for 868 bunches	13	9	0
Total cost.	586	7	0

INCOME

	Rs	A.	P.
Yield per acre in number of fruits, 140984; sold wholesale on the plot itself at Rs 10 per 1,000	1 109	13	0
Subcrop like chillies, etc., taken for the first six months The net profit per acre for such a crop comes to.	50	0	0
Spare suckers sold at the rate of Rs. 10 per 100..	52	0	0
Total income	1 511	13	0
Deducting cost of cultivation	586	7	0
We get a net profit for three and half years.	925	6	0
So, for one year, the net profit for banana cultivation is. . . .	265	0	0

510 - **Means of Promoting the Root-Development of Vine Cuttings in the Nursery.** — PROSPERI, V., in *La Propaganda Agricola*, Series II, Vol. III, No. 3, pp. 33-36, Bari, February, 15, 1921.

In exceedingly dry years, few of the cuttings of Berlandieri and its hybrids take root. In some plantations of Berlandieri × Riparia 420 in Apulia, scarcely 15 % of the cuttings made roots, which means at the present prices, an outlay of over 20 000 *lire* per hectare merely for the purchase of ungrafted vines. In making a vineyard of this variety it is necessary to have cuttings with a well-developed root system.

In order to promote the development of the root system, the author recommends a special treatment of the cuttings which has long been practised in Apulia, and always given good results, although it has been considerably criticised. The treatment is carried out as follows:— The base of the cane that is to be planted must be kept immersed in a basin of water for 4 or 8 days, and then put into light soil, until the time when it is planted in the vineyard.

The author has found that roots develop on cuttings thus treated much more rapidly than on those planted immediately after being taken from the vine. It is also a good way of obtaining ungrafted, well-rooted cuttings, especially in the case of vines which root with great difficulty.

As soon as the cuttings are planted, they must be watered. and the operation should be repeated after some weeks, if the weather continues dry. In the spring of 1920, two adjoining plots were each planted with 11 000 cuttings of Berlandieri × Riparia 420 on the same date (March 1-2); one was not watered while the other was liberally watered on May 5 and at the beginning of April. From the middle of May, both plots were watered periodically, and to the same extent. The number of cuttings that took root was 34 % in the case of the first plot, and 76 % in that of the second.

The author summarises the rules to be observed in making wild cuttings as follows:—

1) Choose suitable soils.

2) Take a well developed cutting of the average length of 45 cm., remove all the buds except that at the extremity which is to make the shoot.

3) Trim the lower end with scissors at the level of the node.

4) Twist the cutting till the cracking characteristic of woody tissues is heard.

5) Keep the cuttings in a basin full of water for 2 hours before planting them.

6) Cover the basal portion of the shoots, when planted, with dung (to which has been added superphosphate and a potassic fertiliser) mixed with soil.

7) Do not put off watering later than the first half of March, and repeat the operation several times before the want of moisture in the soil causes growth to proceed slowly.

511 – An Economical and Rational System of Supports for Nurseries of American Vines.

— ERRICHELLI, E. (Antiphylloxera Consortium of Trani), in *La Propaganda Agricola*, Vol. XIII, No. 2, pp. 25-29, 1 pl. Bari, January, 31, 1921.

It is an undisputed fact that some support should be given to vine stocks but the system which is most economical and at the same time most adapted to the physiological reguirements of the plants has not yet been decided upon. The system generally adopted in nurseries of American vines, namely the arrangement ot the vines in pyramids with a central stake flanked by reeds, is very expensive, and does not encourage the free growth of the canes, so much so that some growers state that American vines produce better grapes when grown without any props, and allowed to spread along the ground.

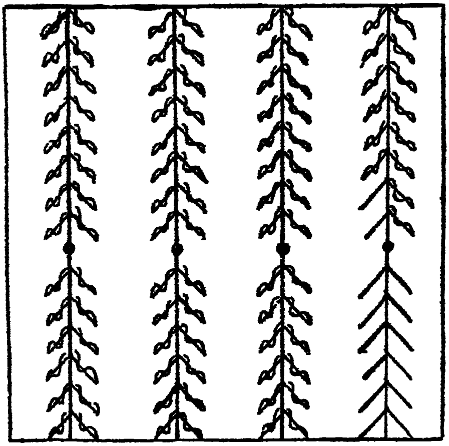
The author suggests a system. which he calls "*a spina*": by this a considerable saving is effected as compared with that of the pyramidal support, and at the same time if the rows face towards the south, the vines enjoy more unitorm and intense insolation, whereas if some other exposure is chosen, the plants are better sheltered from the heat of the sun.

The system is as follows:—

If the stocks are planted from 1.40-1.60 m. apart and in a square, galvanised wire (No. 16 is excellent) is extended between the rows, and attached to a stake at every 25 metres. At either end of the row, a stronger stake is driven in, and fastened into the ground with chains; these stakes need not be more than 8 to 10 cm. in diameter. The vines must be good runners, as otherwise they weigh down the wire arch, and bend it out ot shape. The opposing tension exerted by the arch upon the trellis counterbalances the pull of the longitudinal wire itself. At the foot of each stock, a reed is driven into the ground, the other end being tied to the wire arch in such a manner that it meets the corresponding reed of the opposite row and forms an acute angle with the ground. The slope of reeds thus placed is the same as in the pyramid system.

When the vines canes are tied to the reeds, long "berceaux" are made, from which old or new alleys can branch off without interrupting the course of the longitudinal wire; the wire is placed at such a height as not to interfere in any way with the necessary cultural operations.

The following diagram shows the arrangement of the vine-props just described:—



The cost of trellising 1 hectare of land with 3969 vine stocks arranged in a square (at intervals of 1.60 m.) is shown below.

PYRAMIDAL SYSTEM (WITH SQUARE BASE)

993 trellises for 3969 stocks of 2 *lire* each	Lire	1 984.00
3969 reeds at 80 *lire* per 1000	»	317.52
Carriage of trellises	»	45.00
Sulphate of copper for treatment at 335 *lire* per quintal allowing 6 kg. per 100 trellises, = 59.58 kg	»	199.59
Labour employed 12 days at 12 *lire*	»	144.00
Putting up trellises, 60 days at 12 *lire*	»	720.00
Inserting reeds and tying vine-canes: 40 days at 12 *lire*	»	450.00
Total . . .	Lire	**3 890.11**

If 12 years is reckoned as the duration of this trellising, the annual amortisation (at 4 % would be about 584.45 lire. This allows for the additional expense of renewing the reeds every 4 years (2 renewals), at the cost of 1595 lire.

" A SPINA " SYSTEM.

62 end stakes at 3.40 lire each	Lire	210.80
93 intermediate stakes at 2 lire each	»	186.00
3969 reeds at 80 lire per 1000	»	317.52
Galvanised wire No. 16 at lire 438 per quintal: for the 3 100 m. required, about 132 kg	»	578.16
Carriage of stakes and wire	»	15.00
Sulphate of copper (allowing for larger absorption by the end stakes) 9.54 kg	»	31.95
Cost of labour employed: 2 days at 12 lire	»	24.00
Fixing the end stakes, the intermediate stakes and the wire: 12 days at 12 lire	»	144.00
Inserting the reeds	»	480.00
Total . . .	Lire	**1 987.43**

If the duration of these supports is reckoned at 18 years with the additional expense of 3190 *lire* for replacing the reeds 4 times, the annual amortisation at 4 % would amount to about 408.95 *lire.*

On comparing the two systems it will be seen that the adoption of the second means a saving of about 50 % or 1900 *lire* per hectare.

The system could be modified by using a double number of reeds, *i. e.*, by arranging them so that the tops formed an angle at the foot of the vine-stock, the two upper ends being fixed to the wire so as to make a V leaning towards the latter. In this way, the canes of the same stock would be divided between the two reeds

Such an arrangement would entail a little more expense, but even then, the "spina" system would be much cheaper than the pyramid. It has, moreover, the additional advantage of allowing the vines to grow under the best conditions for their development, for as they have more space at their disposal, they will not be obliged to compete with one another for air, light and heat.

512 – **The Sirah Vine in Italy.** — SANNINO, F. A., in the *Rivista di Ampelografia*, Vol II, No. 4, pp. 49-51. Alba-Leghorn, April, 1, 1921.

The author states that this stock is well worth a trial in new vineyards, and also advocates its cultivation on a larger scale in Italy. It is a French vine that is a great favourite in its native country, but is less grown in Italy, having hitherto only been introduced into the Marches, the Province of Caserta, at the Royal School of Viticulture, Avellino, and in Piedmont. In the three first districts, it has given satisfaction, bud in the fourth, it is not much liked, on acount of its small yield as compared with the local varieties of vine.

All regions with a temperate climate (North and Central Italy, the southern part of Campania on the slopes facing the Tyrrhenian Sea) suit this vine admirably It escapes the white frosts in spring, as it shoots late; it is not subject to non-setting, and its yield is constant Sirah is very resistant to oidium and mildew, and when it does fall a victim to fungoid attack, this occurs at a later date than is the case in more susceptible varieties; further, it is but little affected, therefore treatment is more successful and less expensive. For these different reasons the Sirah vine is much liked in the colder parts of the Avellino district (Forino and Avellino), where the local varieties ripen late and sometimes inperfectly, whereas Sirah (2nd maturation period) often produces a must containing 20 % of glucose.

Its grapes rot easily, therefore this vine must not be closely planted, and should be grown on dry soil with a good exposure, and kept well off the ground. This can be done easily. as it grows very well trained on the maple, as is the custom, for instance, at Potenza Picena, in the Province of Macerata.

In Piedmont, the wine made from the Sirah grapes is less acid than the product of the local varieties; in Tuscany, its good qualities are much appreciated; when the vines grow on calcareous soil, the wine has a high alcohol content, is highly-coloured, and has a fine bouquet.

Sirah does very well when grafted on Riparia, but for dry calcareous soils, 3309 and Rupestris du Lot are preferable.

A large and a small kind ot Sirah are grown, which differ in the size of the grapes and their glucose content; this is higher in the small-berried sub-variety.

513 - **Early Ripening Table Grapes for Cultivation in Apulia, Italy.** — PROSPERI. V., in *La Propaganda agricola*, Series *II*, Year XIII, Nos. 5-6, pp 65-67, Bari, March, 15-31, 1921.

Before phylloxera made its appearance, the cultivation of table-grapes was already a thriving industry in the provinces of Bari and Lecce; the grapes sold wère mostly those of a very early vine, known as "turchesca" in the former province, and "uva rosa" in the latter The more widely extended cultivation of this variety, and the introduction of other kinds which ripen sooner and answer the requirements of the vine-growers better, would be a great advantage to Apulia For this reason, the Government Nursery of Barletta has for the last ten years been studying some of the best known varieties of table-grapes. Of these there are 20 at the present time. The author mentions three: — 1) "Saint Anne of Leipzig"; (2) "Violet Chasselas"; and 3) "Musk Chasselas", which in 1920 (a hot year when grapes matured early) ripened respectively on July 7 July 22, and August 5 (the last being the date of the ripening of the "turchesca" grapes).

In the Bisceglie district, which is the centre of the cultivation of table-grapes, the "turchesca" variety ripens ten days sooner than in Barletta, hence it is likely that the three above-named varieties would also mature there a few days earlier.

The vineyards were planted in 1914-1915 with shoots grafted on Berlandieri × Riparia 420-B., and raised on cordons with spurs. Up to the 4th year of bearing, these vines have shown no signs of bramble-leaf "roncet", a disease to which the "turchesca" vine is very susceptible.

514 - **A Direct Vine Bearer Resistant to Drought the 4643 Seibel.** — CROUZAT, L., in *Revue Agricole de l'Afrique du Nord*, Year 19, No. 80, pp. 115-116. Algiers, Feb. 11, 1921, and in *Le Progrès Agricole et Viticole*, Year, 37, Vol. 74, No. 5, pp. 106-107, Feb., 1, 1920 and Year 42, Vol. 73, No. 2, p. 48. Villefranche (Rhône) Jan., 9, 1921.

For the last 4 or 5 years, the author conducted an experiment on an area covering 5000 to 6000 ft. in several parts of the Department of Aude with the grape variety 4.643 Seibel.

In 1919 and 1920, both noted for excessive drought, the most resistant of all the vine stock in all the vineyards, was found to be 4.643 Seibel and the only vine which apparently did not suffer from the drought was the same grafted on Rupestris du Lot, growing on poor and stoney soil noted for its dryness

In addition to this, in 1920, on the borders of l'Etang de Bages, this variety did not appear to be affected by the salt content, very virulent at the time; in certain plots, the author had observed Carignan species completely defoliated in August.

S. 4643 is a black variety late ripening, excellent yield, giving superior quality wine It is necessary to employ a sulphur wash, and in unfavourable years, one or two sulphate washes. Information has been received from the Gold Coast that in 1920, without this treatment. the leaves were affected with mildew, but the grapes remained undamaged.

Grape resistance is apparently always stronger than leaf resistance.

Success as a result of grafting has been remarkable in every case, the average intake being never less than 94 %. On all the plots under consideration, the branches developed normally with the usual annual spraying (2 sulphate and 2 sulphur).

The proprietors of the 8 plots have grafted this variety quite ignorant of its qualities, and now wish to propagate the same more widely. Their trials were conducted quite apart from each other, but they are all of the same opinion that 4643 is extremely resistant to drought. This was confirmed in 1919 and 1920; what is more, the salt sea winds apparently have no ill effects on on this variety.

LIVESTOCK AND BREEDING

516 - **Diseases of Live Stock in the Northern Territories of the Gold Coast.** — See No 472 of this *Review*.

517 - **The Use of Copper Compounds in the Treatment of Parasitic Broncho-Pneumonia Caused by *Strongylus*.** — VON LINDEN, in the *Deutsche Landwirtschaftliche Tierzucht*, year XXIV, No. 36, pp. 367 368, and Year XXV, No 7, p. 71, Berlin, September 1920 and February 1921.

The treatment advocated by the author is based on experiments extending over ten years.

I. CURATIVE TREATMENT. – Soluble copper compounds may be administered by way of the mouth, or in the form of intra-venous or intra-muscular injections.

The ingestion treatment consists in giving the animal sodium chloride. mixed with 1 % of copper chloride or sulphate. The doses of this mixture ("Kupferlecksalz' which should either be given with the drinking-water, or dissolved and mixed with the food, or in ½—1 litre of water, are as follows:—

(1) For adult cattle over 6 months of age (2) Adult swine	10 gm "Kupferlecksalz" per day per head
(3) Cattle under 6 months old. (4) Sheep (5) Goats	5 gm "Kupferlecksalz" per day per head.

The treatment should last 4-6 weeks and, in order to prevent relapses due to fresh infection it should be repeated twice a week after the animal is cured. This precautions has also the advantage of protecting the animals from contagion when healthy and infected individuals are grazing together, or at times when the disease occurs in an epidemic form.

Treatment by intra-venous or intramuscular injections of a 5 % solution of copper dimethylglycocollate (" Dimethylglykokollkupfer ") has also been resorted to. It is to be recommended for serious cases, or where the state of the sick animals prevents the resorption of the salt by the intestines. Cattle have been given these injections in the following manner :— 10-15 cc. of the 5 % solution were injected twice a week alternately in the muscles of the right and left sides of the croup. Each animal was given 8-10 injections on an average.

II. PROPHYLAXIS. — 1) All animals suffering from coughs and diarrhoea, and coming from infected regions should be isolated.

2) If possible, manure the pastures several times a year with basic slag, or liquid' stable-manure.

3) In cases where infection is to be feared, give " Kupferlecksalz " to all the animals twice a week

518 - **The Clinical Value of the Methylene Blue Reaction and its Use in the Diagnosis of Glanders** (1). — FINZI, G., and CREMONA, P. (Istituto di Patologia e Clinica medica della R Scuola Superiore di Medicina Veterinaria di Torino), in *La Clinica Veterinaria*, Year XLIII, Nos. 17-18, pp. 464-470. Milan. September, 15, and October, 15, 1920.

The author has especially studied, the methylene blue reaction and has compared the chemical results obtained in his veterinary practice with those given by this reagent in the case of human patients. He adopted the technique recommended by RUSSO (*La Riforma medica*, 1905, p. 507) for the preparation of the reagent, and in carrying out his examination. His experiments were made upon the urine of 112 horses, 3 mules, 9 cows, 9 swine and 61 dogs, some of which were diseased in various ways and others healthy, and under different physiological conditions.

The results obtained were as follows :—

The reaction to methylene blue is a very simple test, and the reagent keeps for 3-4 months.

The reaction of the urine has no effect upon the results of the test.

Heating urine to the boiling point does not alter its reaction to methylene blue

In order to be able to interpret the results satisfactorily, the urine should be filtered

Urines with a positive reaction, when no longer fresh (after 2 or 3 days), even if they are filtered, and quite independently of their reaction, lose their power of altering colouring matters to some extent.

When an animal is in good health, the reaction to methylene blue is always negative

---

(1) See *R.*, No 399, 1916, Nos. 73, 191, 660 ; 1917, Nos, 51 and 340 ; 1918, Nos. 56 and 175 ; 1919, Nos. 27, 924, 928 ; 1920, No. 70. (*Ed.*)

The injection of mallein and tuberculin into healthy individuals, as well as the administration of drugs, has no effect upon this negative result.

The test is not specific for any given malady, for it is positive in various forms of disease, whether infectious, toxico-infectious, parasitic, or non-parasitic.

The methylene-blue reaction is positive in the case of all horses suffering from glanders; its diagnostic value for glanders is certain when an entirely positive reaction becomes negative, or only slightly positive if 2 or 3 drops of methyl-blue are added, after the mallein diagnostic test has lasted for 10-12 hours.

519 - **The Diagnosis of Dourine** (1). — I. SANI, L. (Istituto di Patologia e Clinica medica dell'Università di Bologna), in *La Clinica veterinaria*, Year XLIII, Nos. 15-16, pp. 393-403, Bibliography of 27 works. Milan, April, 1920. — II. MARCONI, G., and GASPERI, F., *Ibid*, year XLIV, Nos. 1-2. pp. 1-4. Milan, January, 1921. — III. COMINOTTI, D. (Stazione sperimentale per le malattie infettive del bestiame, Milano), *Ibid.*, Year XLIV, No. 4 pp. 81-91., February, 28, 1921.

I. — THE EXPERIMENTAL DIAGNOSIS OF DOURINE. WASSERMANN'S REACTION. — The author used an aqueous extract of heredosyphilitic liver, which was not capable of fixing the complement without a specific amboceptor. The serum examined, which had been taken from the jugular vein, was rendered inactive, and used as soon as obtained. Diluted active rabbit serum (1/1000) was used by the author as a halmolytic amboceptor against the red cells (1/300) taken from a sheep.

As a complement, fresh guinea-pig serum was employed. From the results, the author concludes that:— The serum of a healthy horse, when in contact with a syphilitic antigen, after being rendered inactive, is incapable of fixing alexine. The serum of a horse suffering from dourine behaves in exactly the same manner as that of a healthy horse. This serum has not the property of affecting the complement in the presence of a syphilitic antigen. In the serum of a healthy horse, or of one suffering from dourine, the natural halmolytic amboceptors for the red cells of the horse are either absent, or are present in minimum quantities

II. — THE CO-AGGLUTINATION OF THE BLOOD CORPUSCLES AND THE MACROSCOPIC AGGLUTINATION OF THE TRYPANOSOMES IN THE DIAGNOSIS OF DOURINE. — From an examination of 15 stallions, which were suspected of having contracted dourine, or were suffering from the disease, or had recovered from it, on the one hand, and from his examination of a healthy stallion and mare (controls) on the other, the author arrived at the following conclusions:—

HAEMO-AGGLUTINATION. — 1) *Auto-co-agglutination between microscope slide and cover-glass.* — This experiment gives no grounds for decision, because a more or less positive result was obtained in the case of the blood of all the horses examined.

---

(1) See *R.*, Jan. 1916, No. 72; *R*, Jan. 1921, No. 60. (*Ed.*)

2) *Auto-and iso-co-agglutination of the blood corpuscles in a water-glass.* — This experiment, however carefully carried out, and although the necessary controls are employed, can never be decisive, even if it is made at different periods, for the phenomena do not always occur during the course of the illness with the same constancy and regularity.

3) *Auto-and iso-co-agglutination of the blood corpuscles in small noso-sero-reaction tubes.* — The results of this experiment are similar to those obtained from the preceding one, but are more varied, owing to the differences in the dilution of the serum

Macroscopic agglutination of the trypanosomes — This experiment offered solid grounds upon which to base an opinion, because: —

1) Changes in the character of the suspensions of the parasites were clearly seen from the moment of their appearance

2) There is a marked difference in the nature of the suspensions themselves when the serum of infected or healthy horses, respectively, are used

3) The agglutinating power of the serum of diseased horses is regularly very high (it may even reach 1 20 000), whereas that of the serum of healthy horses only occasionally has a partial agglutinating effect with a maximum of 1 200.

4) The reaction is caused by the serum of horses which, during the experiments and even subsequently showed doubtful signs of dourine (return of swelling of the prepuce, orchitis and epididymitis, cutaneous plâques, asymmetrical swellings of the eye-lids, and catarrh of the conjunctiva, multiple alopecic areas).

III. — DEVIATION OF THE COMPLEMENT, SACHS-GEORGI REACTION AND MEINICKE REACTION IN THE DIAGNOSIS OF DOURINE. — As the results obtained by the various investigators, who had employed different methods in the diagnosis of dourine (due to *Trypanosoma equiperdum*) did not agree, the author took up the study of the question, and has arrived at the following conclusions: —

1) In the diagnosis of dourine, the deviation of the complement gives one-sided data, for the result of the test is only taken into consideration when the test itself gives a positive result. But the serum of animals showing all the typical chemical signs of the disease (and even where the parasite had been found in the liquid of the vulvular oedema) gave a negative reaction in a large proportion of the cases investigated by the author. The practical value of the reaction is also diminished by the fact that, when the disease is latent, a positive reaction is rarely obtained. The serum test in question, however, can assist the veterinary surgeon in diagnosing tertiary forms of dourine accompanied by serious symptoms and chiefly affecting the nervous system, or principal respiratory passages, in such a manner as to arouse the suspicion that the case is one of glanders, when no certain or long-standing anamnesic data, or information of an epidemiological character can be obtained. It was with the serums of animals that were late in showing any signs of the disease which had usually attacked the nervous system or chief respiratory passages, that

the autho obtained a large proportion (21.4 %) of positive results coinciding with the clinical and epidemiological history of the patients.

2) The effect of curative treatment upon the anti-complementary power of the serum varies according to the case. In certain animals, it is suppressed by the specific treatment, in others, it remains unaltered. Practically, it is best, however, to take a sample of blood for the serum test before beginning the treatment.

3) The SACHS-GEORGI and the MEINICKE reactions are of no use in the diagnosis of dourine.

520 – The Toxicity of the Extract of the Horse-Bot (*Gastrophilus equi*) (1). —

ZIBORDI, D (R. Scuola Superiore di Medicina Veterinaria di Napoli), in *La Clinica veterinaria*, Year XLIII, Nos. 17-18-19, pp. 470-475, Bibliography of 11 works. Milan, September, 15-30, and October, 15, 1920.

The presence of the larvae of *Gastrophilus equi* in the stomach of horses rarely gives rise to any serious inconvenience. This, however, does not mean that the pathogenetic effect of these maggots is wholly negligible, as is supposed by many persons (2). The author has already proved the toxic nature of the extract of *G. equi* and thereby demonstrated the truth of WEINBERG's researches in particular. In the present work he proposed to find out whether this extract had a more complex action.

The extract was prepared as follows: — 20 larvae, after being repeatedly washed in a sterilised physiological solution, were then pounded up in 20 c.c. of pure sterilised physiological solution. The solution was kept for 24 hours in a refrigerator and afterwards filtered through sterilised gauze. The filtered liquid was injected into the jugular vein in 10 c.c. doses.

The injection caused shivering and the evacuation of much excrement mixed with mucus. The pulse and respiration became more rapid, and much subcutanous oedema of the head was observed. After some hours, these abnormal conditions improved, and a few hours or days later, the animal completely recovered. A postmortem examination made at once or 3 months after the experiments, showed no alterations due to the injection.

The author attempted to discover whether these phenomena were simply a manifestation of a toxic nature, or whether they were due to anaphylactic reaction. He compared the results of his own experiments with those obtained by previous investigators and came to the conclusion that the symptoms produced by the injection of the extract of horse-bot larvae in particular and of that of all parasites in general, is to be attributed to substances which are toxic in the ordinary sense, and are capable of acting in such a manner as to cause the death of the animal, without, however, producing visible anatomical lesions. These poisons may attack the cerebrospinal nervous system by preference and, at the same time, act in a special manner upon the heart, almost like a specific cardiac toxin; further, according to WEIMBERG and SEYDERHELM, they may have a haemolytic effect similar to that of a haematic toxin. (1).

---

(1) See *R.*, May 1917, No. 458; *R.*, Jan. 1918 No. 58. (*Ed.*)

(2) Foals out at grass are the animals most frequently attacked and in this case, they show signs of malnutrition, their coat is rough, dark, and devoid of gloss. The mucous membranes are anaemic, the tongue coated, and in certain cases oedema of the legs and lower part of the abdomen is present. The animals are listless, easily tired, and suffer from nervous affections (trismus of the muscles of the jaw, dilation of the pupils and loss of the power of moving the latter). This shows that the disturbances caused by the disease are sometimes so great as to form together with their attendant symptoms a true syndrome. (*Author*)

521 – **A Pathogenetic Bacterium of the *prodigiosum* Type Isolated from the Horse.** — CARPANI, M. (Direttore del Gabinetto Batteriologico Veterinario Militare, Roma), in *La Clinica Veterinaria*, Year XLIII, Nos. 17-18-19, pp. 477-492. Milan, September-October 1920.

Bacterium prodigiosum. Lehmann and Neumann is a micro-organism occurring very frequently in nature; its pathenogenetic characters are usually negligible, and often it is quite innocuous, though it bears a great resemblance to other very virulent forms. The author discovered a new type of the organism in the spleen of a colt that had died at Fara Sabina. He isolated the bacterium, and studied its morphological characters, its reactions to stains, its cultural characters, power of producing disease experimentally, as well as its life-history and antigenic action.

The author proposes the name of *Bacterium erythrogenes equi* for this pathogenic micro-organism which occurs in a red form and in an unpigmented form, both of which, however, are equally virulent.

This bacterium causes serious illness in horses, rabbits and mice; guinea-pigs, rats, and dogs are less affected by it, although they may succumb to its attacks, if it is introduced by inoculation into the serous cavities. It gives rise to symptoms of disease in fowls, which, however, resist experimental infection carried out in all the usual ways.

The action of *Bacterium erythrogenes equi* is more toxic than pathenogenic.

It has many of the general characters of *Bact. prodigiosum.* In its specific characters, however, and especially in its marked pathogenic nature, it resembles: — KOCHS' *Bacillus indicus,* which was isolated from the stomach of a monkey in India: the coccobacillus producing the " mal rouge, " isolated by BROQUET in Cochin-China, where it produces an infectious disease peculiar to the silk-worm moth. It has still greater similarity to SANTORI's erythorobacterium, a micro-organism isolated in Rome from fowls suffering from a form of septicaemia but differs from it in having but a slight pathogenic effect upon the fowls. The similarity existing between these various forms leads to the conclusion that similar bacteria of the chromogenetic group have the power of causing in certain animals, special diseases of a kindred nature, which from the behaviour of the pathogenic agent, as well as from the clinical symptoms and the anatomical and pathological lesions produced, must be classed under the head of haemorrhagic septicaemia. It is thus a mistake to regard the group of chromogeneous bacteria as being composed of ordinary, harmless saprophytes.

---

(1) For a similar action of extracts of *Ascaris lumbricoides.* See *R.*, 1919, No. 1166. (*Ed.*)

522 – **Bovine Coccidiosis in British Columbia; Description of the Parasite *Eimeria canadensis*.** — Bruce, E. A. (Animal Pathologist, Department of Agriculture, Agassiz, British Columbia), in *Journal of the American Veterinary Medical Association*, Vol. LVIII, (New Series Vol. II), No. 6, pp. 638-662, pl. 2, Washington, D. C., March 1921.

A dysentry due to coccidia has been observed on range cattle of all ages in different districts of British Columbia. These cases occurred generally in winter and were confined to the dry central part of this Province.

Out of 165 visibly affected animals 50 died (30 %). Young animals suffered the most severely and often the cases were fatal.

Fatal cases engendered death usually in from 2 to days after showing symptoms and within 24 hours of death are subject to fits, death being in convulsions. The principal lesions are confined to the rectum of older animals and to the small intestine of young calves.

The following treatment was found effective in controlling the disease 50 lb., of mixture consisting of sulphur 2 pts., sulphate of iron 2 pts., salt 6 pts., mixed with 100 lb., linseed oil-cake meal, fed in troughs to 100 head per day for 2 weeks.

The coccidium responsible showed several differences from accounts referring to *Eimeria zurni*, and also differed from the coccidia of New Jersey calves reported by Smith and Graybill of the Rockefeller Institute.

It was designated by the name *Eimeria canadensis*.

523 – **The Treatment of Diarrhoeic Enteritis in Calves with Iodide of Starch.** — Darnaud I., in the *Revue Vétérinaire*, Vol. LXXII, 3rd series, Vol. I, pp. 643-746. Toulouse, December 1920.

The author reports the excellent results obtained by the use of iodide of starch in the treatment of calves suffering from diarrhoeic enteritis. The remedy must be administered as soon as it is made.

The method recommended by Dr. Bru (1) is of a very simple nature, but it leads us to hope that great progress may be attained in the prognosis of this disease: — 3 or 4 drops of 10 % tincture of iodine are put into four spoonfuls of gruel; to this is added as much flour as can be taken upon the point of a knife. The medicine is given to the animals five times a day in the intervals between sucking their dams; it should be mixed fresh each time, just before use.

524 – **Treatment of Sheep Scab by Sulphur Dioxide Gas.** — Kretzschmar, in the *Deutsche Landwirtschaftliche Tierzucht*, Year XXIV, No. 40. Hanover, October 1930.

With the revival of sheep-breeding in Germany, sheep scab has again spread rapidly among the flocks. In order to control this parasite in a more efficacious manner, attempts have been made to replace the present methods of treatment, which have proved inadequate, by treatment with sulphur dioxide, which were used with signal success in combating horse-mange during the War (1).

---

(1) *Revue Vétérinaire*, Vol. LXXII, 3rd Series, Vol. I, pp. 31-32

The Bavarian Society for te Control of Pests (*Bayerische Gesellschaft für Schädlingsbekämpfung G. m. b. H.*) at Munich, has carried out many experiments on hundreds of sheep, with sulphur dioxide fumes of different degrees of concentration. The results obtained were excellent. This Society has constructed a special apparatus of which 3 photographs are given in the text. It consists of a heavy, closed, wooden box weighing 450 kg. in which 4 sheep can be shut up with their heads only emerging through the opening. An indiarubber collar holds the head of the animals. If the sheep have been shorn, 50 minutes treatment with 4 vol % sulphur dioxide fumes is sufficient, otherwise in order completely to destroy the parasites and their eggs on the parts covered by wool a 4 ½ vol % concentration must be used for the same time.

Cost of use of sulphur dioxide,
based on net price of 209.53 *fr. per* 100 *kg.* (*mark taken at par.*)

length of treatment	Boxes (4 sheep per box)	Numbers of animals treated	Amount of fumes used	Cost of fumes used	Labour
— 50 min	1	4	350 gm	0 74	2 persons
8 hrs. 20 »	1	40	3 500 »	7 35	2 »
8 » 20 »	2	80	7 000 »	14 69	2 »
10 » —	1	48	4 200 »	8 82	2 »
10 » — »	2	96	8 400 »	17 63	2 »
8 » 20 »	4	160	14 000 »	29 38	4 »
10 » 20 »	4	192	16 800 »	35 26	4 »

The author does not advise individual sheep-breeders or even Federations of sheep Breeders to build an establishment where the treatment could be carried out, for owing to the very high cost of installation, and the limited field of action of a stationary plant, they would only find themselves out of pocket.

525 - **Goat Coccidiosis in French West Africa.** — Curasson, G., in the *Recueil de Médecine vétérinaire*, Vol XCVII, No. 6, pp. 129-140. Paris, March 1921.

In the course of a recent stay in French West Africa the author met with intestinal coccidiosis in the goats both in the Sudan and in Senegal.

The cause of the disease which been found in the excreta, and again in the lesions, is *Eimeria Arloingi* The malady is a seasonal one, appearing shortly after the rains have begun, and dies out with the return of the dry season. It mainly affects young animals which usually contract the disease in a very serious form; it is very rare for a kid showing symptoms of diarrhoea and loss of flesh to survive longer than a fortnight. In the course of the experiments carried out by the author at Dakar in 1919 and 1920, 26 goats died out of the 31 taken from different herds. Contrary, however, to what had been observed by VELU (1) in Morocco, many adult animals were found to be suffering from such a severe form of the malady, as to cause considerable loss of flesh; the consistency of the dung was also unusually soft. Two old goats died, and the postmortem examination showed them to be infested with the parasite. The symptoms, however, do not differ in any way from those previously described.

---

(1) See *R.*, January 1920, No. 68. (*Ed.*)

The author, however, mentions the frequent occurrence of nervous disturbances which were observed usually the night before the animals died, or on the day of their death. These were not attacks of convulsions preceding the death of the goats such as VELU noticed, but formed a symptomological complex, which was best seen if the recumbent animal was set on its feet. It staggered, its fore and hind legs slid from under it, then it advanced, listless and with its head down describing an arc of a circle of varying radius, when it again fell; on being put on its feet once more, it continued as before.

As remedies, the author has had recourse in vain to emetine, hordenine, the usual intestinal antiseptics and galyl.

The only thing to be done is to try and save the healthy goats by slaughtering the infected ones as soon as the disease reveals itself, and to abandon infected folds and pastures, and avoid damp grazing grounds.

In Senegal, the animals are not allowed to drink at the seianes (2), whch are often used by stock suffering from distomatosis, strongylosis, coccicidiosis, and probably many other parasitic diseases.

526 – The Digestibility Coefficients of the Nitrogenous Matters in the Leaves, Twigs and Small Branches of Trees at Different Periods of Vegetation.

— ENGELS, O. E., in *Die landwirtschaftlichen Versuchsstationen*, Vol. XLVII, Parts V, and VI, pp. 293-355. Berlin, 1921.

The chemical composition and food value of the leaves and twigs of trees have been the subject of much scientific recearch in recent years (3). In many cases, however, the results obtained cannot be compared, because the material had been collected at different times, and the dates of gathering it, a most important factor as regards the results, were not given.

The author used in his experiments a considerable number of trees, the leaves and twigs of which, in his opinion, could be employed as forage He estimated the amount of water, crude fibre, fats, tannin, nitrogenous matter, and nitrogen-free extract they contained.

The leaves and twigs were taken from the same trees at three vegetative periods, viz., in the spring (middle of May) when the leaves had already well developed, in summer (middle of July) during the time of development, and in autumn (middle of October), shortly before leaf-fall.

---

(1) See *R.*, July-September 1919, No. 927. (*Ed.*)

(2) Excavations made by the natives in which the water that collects during the rain remains throughout parts of the dry season.

(3) See *R.* Oct. 1918, No 1136 (*Ed*)

The leaves, twigs, and small branches of 12 species of trees (of which the names are given below), were analysed.

The detailed results of the chemical analysis are set forth in the accompanying Table.

(1) Common Alder (*Alnus glutinosa* L.)
(2) Common Hazel (*Corylus Avellana* L.)
(3) Common Oak (*Quercus pedunculata* L.)
(4) Common Beech (*Fagus sylvatica* L.)
(5) False Acacia (*Robinia Pseudacacia* L.)
(6) Lime (*Tilia grandifolia* L.)
(7) Horse Chestnut (*Aesculus Hippocastanum* L.)
(8) Black Poplar (*Populus nigra* L.)
(9) Sallow (*Salix Caprea* L.)
(10) Common Birch (*Betula verrucosa* L.)
(11) Common Ash (*Fraxinus excelsior* L.)
(12) Sycamore (*Acer Pseudoplatanus* L.)

As regards the nitrogenous matter (crude protein) analysis shows that the amount present is largest in spring, and gradually decreases towards summer and autumn.

The digestibility of the nitrogenous substances and true protein is very high in spring. In nearly all the species, the coefficient of digestibility of all the nutritive matters perceptibly decreases with the progressive growth of the trees

The coefficients of digestibility of the nitrogenous matter in the leaves small branches, and twigs of the different trees at various periods of vegetation are given in the appended Table (see page 593).

The largest amount of protein, which is the most important of the nutritive substances, is therefore secured, if the material is collected during the first half of the summer (from May to the end of July). It is true that if it is gathered later, a little more dry matter and a larger yield is obtained, but this delay entails a reduction in the food value.

The best method, according to the author is to chop up and soak the twigs before feeding them (except for sheep and goats.). The soaked twigs can be mixed with other food stuffs, or else a mixture of chopped leaves, twigs, and molasses can be compressed into cakes. ("Laubfutterkuchen"). The cakes are given to heavy draught horses, 5-6 kg. being fed per head per day with good results.

527 - **Coffee Dregs as a Food for Stock; Experiments made in Italy.** — Brentana, D. (Istituto Zootecnico della Scuola Superiore di Medicina Veterinaria di Parma), in *La Riforma Agraria*, Vol. I, No 7, pp 264-268, Parma, July 1920.

The author alludes to the similar experiments made by Aruck (1), and describes his own. He fed finely-ground coffee dregs from the second infusion to horses, draught oxen, and dairy cows.

All animals, however, will not eat them; horses can be given 0.5 kg.,

of coffee dregs in the place of the same quantity of oats, but very noticeable nervous excitement is thereby produced in the animals.

The cows were of the brown Alpine breed, and yielded 8 to 9 kg. of milk daily. Instead of a ration of 13 kg. of good meadow-hay (consisting for the most part of white clover) + 1 kg. of bran, 13 kg. of coffee dregs + 1 kg. of bran were given to them. The cows at first showed a certain amount of dislike of this new feed, but in the end, they became used to it, and ate as much as 700 gm. per head per day, without experiencing any special effects, the previous slight increase in weight continued, and the milk produced was not altered in any way.

In the case of draught oxen fed on a ration of 15 kg. of good hay + 4 kg. of bran, half of the latter may be replaced by an equal weight of coffee dregs, without the animals suffering the smallest inconvenience.

In short, these experiments confirm the statement that coffee dregs from the second infusion can be used as a stock food.

528 – **Comparative Value of Skim Milk and Whey in Feeding Test.** — See No. 471 of this *Review*.

529 – **The Analysis of the Effects of Consanguinity in the Performance of the Pure-Bred Horse.** — HUTT, F., in the *Fuhlings Landwirtschaftliche Zeitung*, Year LXX, Nos. 3-4, pp. 47-61. Stuttgart, February 1921.

The author touches briefly upon the work of DE CHAPEAUROUGE and his collaborators, RAU, HESSE, GROENEWOLD, SCHMEHL and FRIZEN, whose interpretation of consanguinity was, at the time, readily accepted by German stock breeders. As the question has been treated in a very abstruse manner, it has been summarised in the most important text-books and manuals (1). There are two chief axioms which, as is well known, have been generally believed: —

1) The inbred (intensely bred) animal possesses in a special degree, the qualities of the common ancestry of its parents, and transmits there qualities with unusual certainty.

2) The best degree of consanguinity is in breeding with III-IV *exogamous generations* ("freie Generationen") III-III to V-V ancestral lines ("Ahnen Reihen") respectively.

Ir was only in the last year before the war that a counter-current set in, and the hitherto-accepted interpretation of consanguinity was called in question. The new views are given in a condensed form in the works of OHLY (2) STRUVE (3) STERNFELD (4) and PETERS.

The dominant idea of this opposing theory was as follows: — *Inbreeding, in itself does not affect to any special extent (more than out breeding) the transmission of qualities and prepotency to the inbred animal.*

---

(1) WILSDORF, *Tierzuchtung*, Leipzig 1912,; PUSCH-HANSEN *Lehrbuch der allgemeinen Tierzucht*, Stuttgart, 1911,; KRONACHER, *Allgemeine Tierzucht*, Berlin, 1916.

(2) OHLY, *Studien in der Mennofleischherde Munchenlora*. Berlin, 1920.

(3) STRUVE, *Mitteilungen der deutschen landwirtschaftlichen Gesellschaft*, 1911, Part 12.

(4) STERNFELD, *Deutsche Vollblutzucht*, Berlin, 1917.

This theory is strengthened by two new works by PETERS (1) and PEARL (2) respectively, in which the authors try to solve the question of consanguinity in cattle.

PETERS, who bases his remarks upon numerous data relating to cattle breeding in East Prussia, gives several leading ideas as to the qualities of nearly-related animals and their prepotency. Of these the two most important are: —

1) *The desired qualities are not obtained more frequently by inbreeding than by mating unrelated animals possessing the said qualities.*

2) *Healthy, vigorous, inbred animals transmit qualities at least as well as outbred animals, and are perhaps even more prepotent.*

PEARL found, in the course of his researches on the milking capacity of Jersey cows, that the average number of bulls which were the sires of good milch cows were of the same degree of consanguinity as the average number of bulls with female offspring of inferior milk-yielding capacity.

The author himself has undertaken researches on this question, and has taken as his basis the breeding of pure-blood horses at the private Stud Station at Waldfied, for such breeding best seem to fulfil all the conditions under which it is possible to investigate inbreeding and its effect upon performance.

The degree of the consanguinity of each animal was determined from its pedigree. As was to have been foreseen, all the horses were nearly-related. A small number of stallions, mentioned in the text, figures in almost all the pedigrees as the common ancestors upon which the inbreeding was based. Since these stallions began service, 5-7 generations of horses have been bred; reckoning 10 years for each generation, most of the cases of consanguinity will give 5-7 exogamous generations.

Table I gives the division of the animals according to the different degree of consanguinity.

TABLE I.

Exogamous generations	0	1	2	3	4	5	6	7	8	9	10	11	12
Number of horses belonging to each degree of consanguinity		1	20	34	49	60	6[illegible]	49	5[illegible]	80	4	0	3

With a view to studying the capacity of the animals both for breeding and for racing purposes they were divided into two groups: —

(A) *Brood mares* (judged for their breeding qualities).

(B) *Stallions and mares* (judged for their racing qualities).

(A) *Brood mares.* — This group consisted, neglecting unfertilised and young mares, of 52 animals. In order to judge of their breeding qualities, the author adopted the system of estimating the value of their progeny by their success as race-horses. The total of the performance figures divided by the number of the offspring gave the reproductive value of the brood-mares.

(2) PEARL, A Contribution of Genetics to the Practical Breeding of Dairy Cattle, *Proc Nat. Academy of Sciences*, U. S. A. 1920.

(B) *Stallions and mares.* — This group (after subtracting colts that had died, and animals, whose performance could not be judged on account of their youth) contained 257 animals.

As a criterion of their capacity, the author took the money prizes the horses had won in the various races in which they had taken part.

The money prizes reckoned by the author are the average sums awarded annually at the 22 races marked "important" in the German Racing Calendar.

The total number of horses bred at the Waldfried Stud Station was divided into 6 classes according to their racing powers (these classes are given in Table II.

TABLE II. — *Horses classed according to their racing capacity.*

Classes	Money prizes
1.	123 460.00 francs (*mark* at par) and over

5	1	7	2	14	6	43	1	7	3	22	1	7
6	—	—	1	9	3	27	5	46	2	18	—	—
7	—	—	—	—	2	50	1	25	1	25	—	—
8	—	—										
9	—	—										

The examination of these Tables shows that in the cases of an average and slight degree of consanguinity, the animals capacity is equal, whereas close consanguinity diminishes their racing powers. The Table for the brood mares also shows no relation between performance and the degree of consanguinity. Hence the author is of opinion that inbreeding had no effect upon the racing or breeding performance of the pure-blood horse, and that intense inbreeding had injurious effects.

How far it is permissible to generalise from these results must, however, be shown by further experiments.

532 - Report on Live Stock Breeding in the Northern Territories of the Gold Coast. — BEAL, W. P. B. (Report from the Colonial Office, London), in *Tropical Veterinary Bulletin*, Vol. 9, No 1, pp. 36-50. London, Feb. 1921

As compared with other great stock-raising countries situated outside the tropical zone, the region under consideration cannot be said to be an ideal one, but, under certain conditions, it is more fortunately situated, for example, than Australia. In no district of the Northern Territories is there a genuine water famine ; water can usually be obtained by travelling a short distance. Horse sickness East coast fever in cattle cause ravages in the southern portion of the African continent, but in the Northern Territories have not yet been encountered. The country, however, has suffered from severe epizootics, the principal one being the outbreak of contagious bovine pleuropneumonia in 1912-1913, and rinderpest in 1916-1917, but these outbreaks are, however, not considered to have been so virulent as those experienced elsewhere. The author proceeds to describe the distribution and administration of the different areas with their provinces and districts, and also the physical conditions prevailing.

The White Volta is the chief river of the Protectorate, and this and the other rivers contain water throughout the year.

The climatic conditions of the Northern Territories show a relatively high solar maximum point but a mean of 77°, two seasons; 3 months of heavy rain, 3 months of showers and 6 months of dry weather.

I. ORIGIN OF THE PRESENT-DAY LIVE STOCK AND METHODS FOR REARING. — Cattle, sheep, goats, horses and donkeys are believed to be of recent introduction. — The only tribes which raise livestock are the Peuhlish people, and the descendants of Peuhlish marriages and the Peuhlish themselves are immigrants from foreign parts. These people and their descendants certainly introduced the zebu ox, the present day breeds of sheep and goats, the horse and donkey, but the Taurine type of cattle found in the Territories is believed to be of different origin.

The methods of rearing as practised by the natives are crude and unsatisfactory. There is no division of the herds or flocks, no provision is made for the foraging of stock during the dry season, the animals have to depend entirely on the grazing obtainable and the only care taken is to supply them with water, often very inferior. Dietetics, selection, and other hygienic principles are unknown.

II. GRAZING AND FEEDING. — The grazing lands are unfenced and are the common property of the peoples, irrespective of whether they are the indigenous races or immigrants importing and driving cattle to Ashanti and the Gold Coast Colony.

During the rainy season and up to the end of November, there is no scarcity of grazing and it is good and abundant. After this time, the ground becomes dried, all the grasses become dry and brittle, except in pastures in the vicinity of rivers and swamps. The country now begins to be " fired " and gradually becomes a black waste. As regards the chemical composition of the soil, in the low lying countries there is a deficiency of carbohydrates and phosphates In the northern zone the cattle are distinctly larger than those of the southern zone, and their size is believed to be due to the greater quantity of carbonates and phosphates in their fodder. The grasses hitherto identified comprise the following: — *Cenchrus catharticus* Del.; *Digitaria horizontalis* Willd; *Eleusine indica* Gaerth; *Eragrostis ciliaris* Link; *Pennisetum purpureum* Schum. (These were identified by CHIPP (late assistant Conservator of Forests, Gold Coast). The following were identified at Kew: — *Cymbopogon rufus, Eragrostis aspera, E. tremule* (*Iryza sylvestris*).

The seeds of 19 other species were collected and remain to be identified.

III. STOCK BREEDING. — (1) *Cattle.* — The breed of cattle in the Territories is the humpless (taurine) type A few of the humped (zebu) breed occur and are usually confined to the division bordering on the northern frontier of the Protectorate. Crosses between these two breeds are fairly numerous, especially towards the northern frontier. The origin of the taurine type, which is identical with that found indigenous to Dahomey and French Guinea is a debatable subject PECAUD considers that the type is indigenous to Central and West Africa; CARDEMOY and WELLAERT state that it is of Asiatic origin. COSSAR EWART has examined the skulls of this breed and believes it is of Celtic short horn origin. The author agrees that there is a great similarity between this breed and the British-shorthorn, although the west African breed is degenerate, due to interbreeding and climatic conditions.

The cattle are small, symmetrical, compact animals very much like a miniature shorthorn. They are slow to mature and reach their full size at the age of 6 to 8 years Bulls and bullocks, when allowed to reach their full development, turn out to be very fine animals, and for their size would be able to compete against some of the European small fancy breeds, such as Dexter-Keny cattle Heifers become sexually mature at from 18 months to 2 years old, bull calves at 15 months. Calves as soon as they can graze *i. e.* at about 3 months old, are muzzled with spikes in certain districts to prevent them from sucking, and the mother thus dries off and comes into season again, so as to produce calves yearly. It the cow is left to herself, she will give milk from 6 to 9 months and comes into season from 6 to 12 months after calving. A good milking cow gives on an average about 2 pints of milk a day.

The averages of the various body measurements of these animals in the different districts are given as follows: Average age 7 years; length of body to shoulder 46 in., to muzzle 65 ½ in., girth behind shoulder 54 ½ in., in front of back 55 $^3/_4$ in., length of forearm 11 in., length of thigh 14 $^3/_4$ in., bone below knee 6 $^3/_4$ in., below hock 7 in., head length 16 ¼ in., breadth 7 ¼ in., width across loins 13 $^3/_4$ in.

The chief colours are black, and black and white. Brindles are common and when seen are grey. Red and white, and yellow and white also occur.

The shape of the horn varies from right angle projections to those that curve downwards, forwards and backwards into lyre shape. The feet are usually black, but should white be very predominant, the feet are white or white and black. The breed is a hardy disease-resisting animal and a very good feeder and forager. The meat, although of good quality and taste, lacks marbling. In the hilly regions and on stony ground it runs into a bigger animal; in the north along the frontier it is probably mixed with zebu blood, but has lost the characters of that breed. The chief faults in connection with the breeding of these cattle are : interbreeding, commencement of breeding at too early an age, starvation of calves, improper feeding of cows during lactation, no regulation of calving time, abundance of ticks on cows, and the infection of cattle with disease while they are young especially blood diseases.

B) *Sheep*.—The only breed found in the Northern territory is probably descended from the Karakul breed of sheep in Asia, but has lost its characteristics through climatic conditions also by prolonged inter-breeding.

Small wire-haired, sheep are produced colourp ure white, or white and black, or an admixture of white and black. No mixtures of red and white or yellow and white are seen as occurs in the Fulan or Lagos breed of sheep. The males are furnished with good regular-curved horns have a crest of hair on their neck, and a long beard of hair running from the jaws to the breast. The ewes sometimes possess a straight stump of horn and have a good and well-shaped udder. The newly-born lamb exhibits the peculiar curl of its hair which is characteristic of the Karakul breed. This curl is lost soon after birth, and a month afterwards the hair is entirely straightened out. The fault of the breed lies in its small size and lack of taste. Considering the fact that sheep-breeding is a profitable industry for the Territories, the introduction of foreign blood is advised in order to improve the nature breed, *e. g.* the Karakul and Merino breeds, and a start might be made with Merinos and Dorsets; the fleece would be a drawback in a hot climate, but they could be kept in the open, country and not in the forest country where the climate is hot and damp.

C) *Coats* — Probably of Asiatic origin. Very small misshapen, animals due to many generations of inter-breeding; general colour brown usual caprine style of horns; females frequently of bad shape but they possess good udders and give plenty of milk to their young. The breed is fast degenerating and the introduction of the Angora breed of goat is recommended for improvement pusposes.

D) *Horses* — Probably introduced by the Peuhls. From the shape of the head and ears, the horse is probably of Arab origin. The colours are chiefly bays, then blacks, chestnuts and roans. As a rule they are wanting in bone and good hind quarters; they run up to 14 hands high, but 13. 2 1/2 hands is the average size. Very few stallions are castrated; the mares are degenerating and no selection for service by good stallions is practised.

Horses are, however, better cared for than other domestic stock. They are given an extra diet of groundnut hay, and pea and pea hay during the dry season when grass is scarce, and if used for riding they are given guinea corn (*Sorghum vulgare*) or millet.

Measurements of stallions in different districts varying in age from

7 to 14 years are given as follows: height 13 to 13.3 hands, bone 6 ¼ to 8 in., girth 62 ½ to 68 in. The horse bred is therefore small in spite of the fact there is no inter-breeding. This is attributed to two reasons: (1) Absence of selection of sire and (2) deficient dietetics.

If the stallions are to be improved for draught purposes the author considers that one of the small heavy breeds such as the French Percheron should be introduced.

E) *Donkeys.* — Also of recent introduction. Donkey breeding is on the increase. The animals are fair sized compared with other livestock, hardy and willing to work, light in colour with the characteristic spinal stripe and frequently with shoulder and leg stripes. Average height 12 to 12.2 hands. The female possesses a good udder and gives a good deal of milk to her young. Feeding is very similar to that of horses, no selection is made for service, but very little inter-breeding goes on as donkey breeders are continually purchasing new animals or exchanging donkeys for cattle and sheep. Donkeys are used as pack and riding animals.

F) *Pigs.* — Very few pigs are bred in the Territories. The chief pig breeding part is in the Kacomba country, Yendi District. The animal is probably descended from the wild wart hog, (*Phacochoerus*), frequently seen in all the swampy areas. The animals are small and black. The sows farrow easily and have large litters, often 11 or 12 in the litter.

G) *Poultry.* — Fowls, ducks, turkeys, pigeons, guinea fowls, and ostriches are all bred in the country. The native fowl is described as a small hardy bird, of almost every colour, with game features predominant. According to the author they can be readily improved and the best cross would be with game and Orpington birds.

IV. INCREASE AND DECREASE OF LIVE STOCK. — The losses are at present very serious, and amount at least to 35 %, made up of 22 % attacked by disease.

V. ENTOMOLOGICAL SITUATION AND THE MORE IMPORTANT EPIZOOTIC DISEASES OF LIVE STOCK. — The entomological situation is discussed and its relation to the livestock industry, and a detailed description is given of the epizootic diseases.

The author observed during tour of inspection 3 species of tsetse fly, viz. *Glossina morsitans*, *G. tachinoides* and *G. palpalis*, but these are limited to the river banks.

The more important epizootic diseases include: anthrax, contagious bovine pleuro-peneumonia, contagious foot-rot, epizootic lymphangitis, filariasis, fowl cholera, piroplasmosis, rinderpest, haemorrhagic septicaemia, and trypanosomiasis. Filarial infection is transmitted by some species of *Culex*. The most frequently found piroplasms of cattle in the Northern Territories are: *Piroplasma bigeminum*, *Theileria mutans*, and a third piroplasm, which is occasionaly met with and which has been identified provisionally by MACFIE as a species belonging to the genus *Achromaticus*. These parasites set up merely benign affections, seeing that all calves become infected shortly after birth.

[522]

T. parva, the cause of East coast fever of cattle has not, according to the author, been discovered in the country, in spite of frequent search, A tick which is capable of producing its spread, viz. *Rhipicephalus simus*. exists and would represent a serious factor if the disease should ever be introduced.

The horse is also said to be subject to infection with *Nuttallia equi*. which produces a dangerous anemia frequently terminating in death, Up to the present time piroplasmosis has not been detected in sheep.

Three types of trypanosomiasis are known to occur in the Northern territories viz. *T. brucei* (*pecaudi*), *T. vivax* (*cazalboui*) and *T. congolense*. The symptoms caused by all 3 species are very nearly the same in horses ; but infection caused by *T. vivax*, however, is not so severe as that caused by *T. brucei*.

Atoxyl is considered to be undoubtedly the best drug to use for treatment, combined with good nursing and feeding, in cases that are not too far advanced. In cattle, *T. vivax* does not appear to cause much harm and no symptoms were observed ; *T. brucei* is said to cause a sudden emaciation, which becomes chronic and lasts for a year, after which the cattle gain some degree of tolerance towards the infection and commence to put on flesh again.

T. congolense was first discovered by the author in the country in 1912 and hitherto had only been found naturally in horses, in which all the chief symptoms of trypanosomiasis were seen. By experimental inoculation it was found very fatal to sheep, goats and dogs.

VI. CATTLE TRADE. — This trade appears to be small and many more cattle could be exported if the herds were increased. It is estimated roughly that the trade in indigenous cattle for the year 1919 could be represented at 2000 head.

VII. ESTIMATED LIVESTOCK CENSUS AND VALUATION IN THE NORTHERN TERRITORIES AND YENDI DISTRICTS

	Heads	Total Value	Average price per heed	
		£	£	s.
Cattle	68 500	548 000	8	
Sheep and goats	150 000	75 000	—	10
Horses	1 097	10 970	10	
Donkeys	2 003	10 015	5	
Pigs	321	963	3	

533 - **Private Stud Stations Versus State Stud Stations.** — I. MOMMSEN, in the *Deutsche Landwirtschaftliche Tierzucht*, year XXIV, No. 47, pp. 485-487. Hanover, November, 1920 — II. DE MONICAULT, P., in the *Journal d'Agriculture pratique*, year 85 New Series, No. [illegible]p. 169-170. Paris, March, 1921.

Before the war, it was in the interest of the State to provide good remounts, and no expense was spared in order to be able to supply horse-breeders with first-rate sires (whole-blood, or half-blood), the service-fee being always very moderate. On the other hand, the State has never cared, and does not care to-day, to take measures for the improvement of carriage, or cart-horses, and any progress that has been made in this direction is entirely due to private initiative. In this branch of horse-breeding the participation of the State hinders all work of improving the breed, for the competition of the Government, which provides inferior stallions at very low service-fees, prevents, or at least hinders, the work of any really good, private Stud Station.

The author shows the inferiority of the State Stallions by the following figures: —

Show-Sale by auction of horses in the Province of Saxony. — Of the 65 stallions competing at the show in 1916, 23 were the offspring of privately owned sires; there were no colts by State Stallions.

Of the 77 stallions competing at the 1917 show, 18 were by private sires, 1 by a State sire.

Of the 88 stallions competing at the 1918 show, 22 were by private sires, 1 by a State sire.

Of the 36 stallions offered for sale in 1918, 2 only were by State sires.

Of the 33 stallions offered for sale in 1919, 3 were by State sires.

Of the 98 stallions entered in 1916, 22 were by private sires and 4 by State sires.

On the 105 stallions entered in 1917, 27 were by private sires and 3 by State sires.

Of the 123 stallions entered in 1918 (1), 27 were by private sires, and 4 by State sires.

During the years in question 150 State sires, and 100 privately-owned Belgian sires were placed at the disposal of breeders.

The author brings out the fact that at a time when the State has very limited means at its disposal for the encouragement of horse-breeding, it still wishes to saddle itself with the heavy expense of keeping up Government Stud Stations.

He insists upon the necessity of giving up National Stud Stations into the hands of breeders, which in his opinion can best be effected by selling the existing establishments, at moderate prices, either to the Provinces, or the Chambers of Agriculture. As soon as they have changed hands, the Stud Stations should be re-organised upon a paying footing, so that the large grants hitherto made to them may be used for the encouragement of private stallion-keeping, which would soon revive.

II. — The breeders of half-blood animals having asked for a draught-horse stallion, a request which cannot be satisfactorily or immediately granted, the author has attempted to suggest a solution of the problem.

The inpossibility of further increasing the Stud Stock by at least 400 horses, owing to lack of credit, premises and stable-hands, means a decrease in the number of privately-owned stallions.

---

(1) The other stallions came originally from Belgium and the Rhine Provinces.

According to the author, the problem to be solved is how to receive the private Stud industry, which has tended to disappear owing to the following reasons: —

1) The service-fee cannot be raised by private stallion-owners in proportion to the increase in the general stud expenses, and to the sale price of mares and even of horses, because the Government, which always has a Stud Station in the neighbourhood, keeps the service fee too low, and becomes a formidable competitor.

2) The premiums granted to stallion-owners have been raised but little since the war, and are insufficient to compensate for the increased expenses of the private Stations.

3) Stallion-owners, not having been able to keep their stock during the war, have been disinclined to make the necessary effort to reconstruct their stables now that the war is over (there being an enormous difference between the prices the animals fetched in 1915, and the purchasing prices in 1919 or 1920)

Instead of requiring the State Stud Stations to increase their already large stock by the addition of 400 new animals, which would entail an annual out-lay of 4 000 000 fr, the author thinks it would be better to raise the grants made to private stallion-owners, and to assist them in the purchase of sires

Such measures, if carried out without loss of time, would allow of the rapid reconstruction of private Stud Stations.

AN ACCOUNT OF THE TESTING OF MILCH COWS. — Denmark was the first country to form milk Cow Testing Associations These are closely connected with the co-operative movement, which is greatly developed there, and is the cause of the extraordinary progress of the export trade in animal food-products. Before these Associations were established, it was, however, necessary to make many and definitive experiments in the feeding of dairy cows, in order to discover the relations between food and milk production.

The first Testing Association was founded in Denmark in 1895 and in Germany in 1897 (1). Since that date they have extended over Europe and in other parts of the world. The object of these Associations is to furnish the agriculturist with technical information as to feeding and rearing his stock, and especially to teach him how to determine the *relative yield* of dairy cows, the *cost of feeding them*, the amount of food necessary for obtaining milk of the same weight or fat content (other conditions being equal), and by these means to enable the breeder to select the most thrifty animals which can also be used for breeding purposes (2).

The relative milk yield is usually determined by taking 3 factors as a basis *i. e.*, the price of food, the " nutritive units, " and KELLNER's starch equivalents. The author shows briefty that the first two factors are erroneous, and discusses the value of the third

As is well-known, KELLNER maintains that the starch equivalents give a sufficiently exact method of determining the utilisation of the food, even from the points of view of milk production. The author, however, does not agree with him, and very justly remarks that KELLNER has not allowed for the specific action of different foods upon the milk yield and demonstrates the troubles due to this fact by the help of experiments. The total effect of a ration upon milk production depends upon the feed in its entirety, and not upon its starch equivalents.

Nevertheless, in spite of the inadequacy of the starch equivalents system from the dairy-farmers' point of view, the author is obliged to adopt it in default of a better, but he shows the importance of directly measuring the effect of the most important foods upon milk production, by means of systematic experiments carried out on a large scale, and with the object of obtaining a basis for the compilation of better forage-tables for milch cows than those existing at present.

There are, however, many other difficulties connected with experiments relating to milk production. The milk tests and the estimation of the food consumed are generally made but twice a month, and are inaccurate, seeing the impossibility of directly determining the amount of food eaten in the meadow. Only approximate results can be obtained. Since the milk yield varies at the different lactation periods, the author advises that breeding-cows be discarded only if they have given bad results in 2, or better, 3 successive periods of lactation.

---

(1) On May 1, 1914 Germany boasted of 792 Testing Associations, with 13 219 members. The number of cows tested was 351 857 Cf. HAUSEN, H., *Die Milchviehkontrolle in der Rindviehzucht des Deutschen Reiches*, Berlin, Parey, 1916, p 20.

(2) See, G. PUSCH, *Die Beurteilung des Rindes.* Berlin, Parey, 1910, p. 321. (*Ed.*)

Another circumstance which renders uncertain the testing of relative capacity is the fact that "individual feeding" is but little practised (1).

The author is of opinion that it is unwise to insist on judging a cow's milk-yielding capacity solely from tests, as is at present the custom, and he is no advocate of entering the results of relative milk-yield tests in the Herd book. If a milk-production competition is part of the Show programme, other necessary qualities must not be lost sight of in awarding the prizes, viz., 1) the absolute milk yield (which should increase *pari passu* with the relative yield); 2) the health of the animals; 3) their symmetry; 4) their pedigree.

Nevertheless, it cannot be denied, that the testing of dairy cows has yielded excellent results. It has even contributed to an increase in the average milk production of farms (2). These results obtained by the testing Associations must be attributed in the main to the diffusion of practical instruction, both in the feeding and rearing of cattle.

The author is frankly averse to the determination of the relative yield, and he concludes by stating, that the testing staff should be equipped with more specialised and thorough scientific knowledge, in order to be in a position to impart useful information to the breeders as regards the feeding and selection of their stock. He also says that they should be adequately paid.

II. — RESEARCHES ON THE MILK PRODUCTION OF SIMMENTHAL COW. — SCHMID states that in order better to judge of the quality of these animals, the milk-testing trials at Agricultural Shows should be more numerous. The Central Administration of the Liebefeld Station devotes special attention to milk control with a view to rendering it more general in Switzerland.

KAPPELI has even taken the trouble to collect the data of the milk production tests made from 1899 to 1914 in the Liebefeld cow-sheds, and he thinks that a test made twice a month (using a sample of the morning and evening milking) would be enough for the determination, in a sufficiently accurate manner, of the milk yield during each period of lactation and also of the quantity of milk given by each cow (3).

(2) On the transmission of the qualitative and quantitative milk yield, See H. WERNER, *Die Rinderzucht*, Berlin, Parey, 1912, p. 506, and *R.*, Feb. 1920, No. 230. — M. COQUIDE, in a recent publication (*Améliorations des plantes cultivées et du bétail*, 607 pp., numerous figures; Paris, Baillière et fils, Encyclopédie agricole, 1920), without denying the importance of increasing milk production by the direct means of selection, also states that it is difficult, to estimate it practically, but he does not think that the importance of correlative characters is lessened.

NILS HANSSON has written a work dealing with milk-testing in Scandinavia entitled *Kontrollforeningarnes arbetsfält*. E Jansson, Malmo. — See also *R.*, Feb., 1921, No. 177.

For results obtained in Denmark, See *The Agricultural Gazette*, 1920, No. 2. (*Ed.*).

Since 1919, the results of these milk trials have been entered in the Liebefeld Herd book.

III. — THE NEED FOR TESTING MILK PRODUCTION IN FRANCE. — BRUNO thinks that rigorous individual testing of milk production and butter yield should be instituted in the liberated regions of France, where there are now large numbers of cattle of different origins. The author suggested the founding of Testing Associations ; special attention being paid to the fat content which should be estimated according to GERBER and FONARD's methods.

IV. — SUGGESTION AS TO THE USE OF TESTING THE MILK SUPPLY FROM A STOCK-BREEDING POINT OF VIEW, IN GERMANY. — ABL regrets that the war has so greatly decreased the importance of the Testing Associations which were formerly in a most flourishing condition, and considers that it is now more than ever necessary to use every means to restore them to their previous influential position. The stock breeding principle lying at the base of testing, and which has hitherto been regarded as all that is needed for rearing selected animals, should be applied to the mass of the cattle.

The author inclines towards compulsory testing, but he fears that the Unions, if left to themselves, would proceed to extremes, and only aim at great individual milk production, which if carried to undue lengths, would be detrimental to the health and vigour of the race. It is clear that testing should also be extended to the mountain races, but hitherto all the data as to milk yield have remained in the hands of the breeders. PETERS is well aware of the importance of these data, which would form a useful basis for estimation

The author has devised a new scale of points which he suggests should be used in judging dairy cows at shows. He divides the animals into different classes according to their absolute milk and fat yield relatively to 100 starch equivalents. The marking for absolute yield, in proportioh to the annual milk production, is limited to the " recognised healthy optimum, " which may vary with the breeds and localities, after which the number of points decreases with the further increase of the absolute yield. On the other hand, the points for the relative yield, which is expressed here by the fat content of the milk, increase in a continual and regular manner from the minimum of 1 point for the yield of 2.5 to 5 kg., of fatty matter per 100 starch equivalents, to the maximum of 7 points for 9.1-9.5 kg. of fat per 100 starch equivalents.

These points, which mark both yields, should be settled each year by the control staff, and ought to be an indispensable condition of the registration of the cattle in the Herd-books. The system adopted by breeders of the Simmenthal and Glan breeds, and to some extent by those rearing Francken cattle during the last decades, shows the danger to which the health and vigour of these animals is exposed, and gives occasion to fear, that the objects aimed at in breeding these valuable races will thereby be defeated.

V. — MILK YIELD AND THE METHODS OF DETERMINING IT. —

GUTH points out that hitherto the absolute yield of milk and fatty matter is tested in Bavaria (this test is called the *examen*) whereas in North Germany the relative return is determined (*contrôle*). In the latter region, however, a large number of concentrated commercial foods are used, and in the *contrôle*, no importance is attributed to the basal bulky fodder. In Bavaria, on the other hand, these concentrated foods are little employed, and it is still necessary to take the farm fodder into account and to continue to determine the absolute return. (*examen*).

PROBST, also thinks, that the *contrôle* of the relative production should afford the breeder some assistance in judging of the absolute production.

VI. — PRIZES AWARDED FOR YIELD BASED ON ACTUAL PERFORMANCE IN GERMANY. — DRIEHAUS recalls the fact that in nearly all the districts where the plain breed of Pied Black Cattle were kept, experiments were made before the war on the basis of the absolute yield of milk and butter fat. In some cases, a system of awarding the prizes was adopted which combined both methods, with the idea of putting the relative fat content of the milk before the total yield of fatty matter. Some districts even reckoned the parents to the credit of the animal and thus placed selection according to milk yield upon a solid basis.

At the Lüneberg show, there were 10 classes for cows and 1 for bulls. In order to be admitted into the latter class, it had to be shown that the dam of the competing bull had yielded 110 kg. of milk fat during the 1st lactation period, 130 in the 2nd, and 150 in the 3rd. The classification of the cows began with yields of 110-120 kg. of fat during the 1st lactation, period, up to 170 kgs., and over during the subsequent periods Further, the testing had to last 1, 2, or 3 years. Thus the first class consisted of cows that had been tested for 3 years at least, and had given from 150-170 kg. of fatty matter per annum ; whereas the 10th class was made up of cows that had only been tested for one year, and had supplied from 100 to 120 kg. of butter fat during their first lactation period.

Although this system is not without its defects, it has the advantage, according to the author, of making symmetry and milk yield correlative characters.

There then follows a criticism of the suggestion made recently by the German Society of Agriculture to the effect that, in future, the average yield of the competing animals or groups of animals, should be taken into account in awarding prizes, to the exclusion of the individual characters of the cattle. This proposal had already been criticised by HANSEN and other authors.

VII. — THE AWARDING OF PRIZES FOR MILK YIELD IN GERMANY. — HULSEBECK congratulates the German Society of Agriculture on having acceded to the wishes of intelligent cattle-breeders who desired that the animals should not be judged merely by their exterior, but that the actual milk yield should also be taken into consideration.

The first time that prizes were adjudged for milk production was in 1913 at the Show held at Wittenberg, on which occasion KOFAHL decided that the judges were not only to take into account the symmetry of the animals exhibited, but also their actual milk yield, and that of their ancestors to the 2nd generation, in the case of cows, and to the 3rd in that of bulls. The author gives the number of points credited for each of these characters.

While agreeing with the censures passed upon the award of prizes according to the average of the farms, the author considers it most encouraging that the system of rewarding the highest milk yield should have been officially recognised by the German Society of Agriculture, which will doubtless, as Hansen has already said, not fail to improve this system after the results of the approaching shows have proved its value.

VIII. — Cow-Testing in Canada — Nothing is more useful than to increase the milk yield of a cow, but this can only be done when the breeder knows the exact amount already given by the animal. The Dairy Branch of Canada has interested itself in this question since 1904, and has published regulations on the subject since the spring of 1918. In each province, with the exception of British Columbia, the Dairy Branch has placed a competent officer to whom has been entrusted the task of organising Dairy-Cows Testing Associations.

In 1919, there were in Canada already 22 517 cows under the supervision of the Branch, of which 10 374 were in Quebec Further, thousands of test-forms were asked for by unorganised breeders, who were evidently engaged in selection work on their own account.

White estimates that the effect of the work of the Dairy Branch has been to increase individual production by 30 %.

The object of testing the cows is to be able to obtain qualitative and quantitative data respecting the milk yield of each animal. These data are also an excellent guide for the breeder who practises cattle selection.

IX. — Organisation among farmers in Ohio, U. S. A. — Erdman describes the Economic and Agricultural Improvement Associations of the State of Ohio, and has co-ordinated all the information he obtained in the course of his visits to different farms, and by written and verbal enquiries. His reports deal with Purchase and Sale Associations, Agricultural Production and Improvement Societies, and Mutual Benefit Associations. The production Societies are divided into 2 groups, one of which consists of growers of cereals and owners of pastures, and is chiefly concerned with the improved economy of labour, while the other is composed of the manufacturers of butter, cheese and canned products. Among the organisations for the improvement of agriculture, the author mentions the Agricultural Bureaux, of which the chief objects are to increase production and to improve the conditions of rural life, Associations engaged in increasing the stock of cattle, in milk-testing, providing a service bull, increasing herbaceous and arborescent crops, and finally those Associations that arrange fairs and markets.

The first milk-yield testing Association in America was founded in 1905, at Fremont, Michigan. In Ohio, the first was instituted in 1909, and by 1917, there were 31 of these Associations, though since the war their number has fallen to 26. The tester, who is paid by the Associations, has to test the milk once a month.

The good effect of testing upon the increase of milk production is shown by the following figures relating to the Bornesville Association (which has been taken as a type).

Years	Average number of cows	Average production per head	
		Milk Lb.	Butter Lb.
1914–1915	350	5 793	289,8
1915–1916	301	5 594	283,4
1916–1917	364	5 923	308,5
1917–1918	351	5 974	313,9
1918–1919	290	6 845	345,4

536 - **Roman Cattle.** — Bianchini, B., in the *Rivista agricola romana*, Vol. XLVII, No. 34, pp. 91-109. Rome, March-April, 1921.

In Latium, cattle-breeding suffers much from the competition of sheep-breeding, which accounts for the fact that there are only 11 head of cattle per sq. km., a very small number for so large a province.

Two methods of cattle breeding are practised: — (1) Free grazing in the case of the pure local breed (the Podolian stock): (2) stabulation in that of imported breeds (Swiss and Dutch). The latter give a large amount of milk which, however, is much inferior in richness to that yielded by the Roman cows.

When the former system is adopted, the herds always remain in the open, and graze in the uncultivated fields and low marshy meadows, or even in the woods, where the cows usually pass the winter after calving. Cattle can turn to good account the shrubs and coarse grass that sheep refuse to eat.

The method of breeding practised is in-breeding and selection, and it is owing to this system that the Roman breed is the same to day as it was 19 centuries ago. Long inbreeding has given rise to no deterioration of the stock.

The characters of the Roman cattle are those of the Podolian race. The calves at birth have a wheat coloured coat, which only later assumes a lighter or darker shade of blue-grey. The height of the bulls varies from 1.50 m., to 1.68 m., and their live-weight is from 7 to 12 quintals.

Cows used for breeding purposes are known as " vacche da vita, " vacche da corpo " or " da frutto." Those weeded out annually on account of age or sterility, are sent to the butchers, and are called " cacciatore. " In the trade jargon, distinction is made between the " tronco delle vacche sode " (the group that has not yet calved) the " ambasciata delle vacche figliate, " (cows with small calves) the " partita delle mongarole " (the milch cows), the " branco dei torazzi. " (herd of young bulls), which are known under this name until they are 2 years of age; the "bravazzame," or calves of 6 months to 1 year, which are to be reared. At the age of 1 year, the calves are called "asseccaticci," later "biracchi," after being castrated they are known as "giovenchi" (young steers), and after thy have been trained (when 5 years of age), they are called "buoi" (steers) The steer works until it is 12-13 years old; when past work it is called a "camarro," and fattened for the butcher. The heifer of 2 to 3 years of age is called a "nutola" or "annutola." When 2 years old, it is served for the first time by the bull; after the second calving the animal is termed a vacca (cow).

When the bull has completed its 7th year, it is castrated otherwise it would be a dangerous animal. After this operation, it is known as a "maglione."

The calves of the "nutole" are never kept; they are allowed to suck their dams until they attain the weight of 200 kg. (Royal Decree of April 22, 1914, No. 49, and May 2, 1914 No. 506), when they are sent to the abattoir.

The Latium cattle seldom suffer from disease. Tuberculosis is almost unknown among them, they are little and very rarely attaced by infectious diseases, but they are much troubled by parasites.

They are chiefly used as draught animals, and in the present conditions of Latium, it would be impossible to find substitutes for them.

Their capacity of milk production leaves much to be desired. The average length of the lactation period is 7 months, 4-5 litres of milk being usually given daily, although some cows yield more than 8-10 litres, which proves that the perfomance of the breed could be much improved by selection, and still more by growing forage crops. The milk is excellent, much superior to that of the Swiss and Dutch cows kept at the dairy-establishments on the outskirts of the town. The specific gravity of the Roman cows milk can be as much as 1.037, it contains 6.5 % fat, and about 6.9 % of casein.

These unbroken cows are milked "alla rimessa," that is to say, in the open, in a quadrangular space surrounded by walls a or a "puntone" which means, in an angle formed by the meeting of two partitions.

The cow-herd ("vaccaro") of each group of 15 cows ("partita") milks his own cows, usually at 10 a m., and at 10 p. m. The animals are driven into the "rimessa," or "puntone," by the "appressataro" (1). When they enter, the cowherd calls each cow by its name and as soon as it, approaches throws a rope over its horns twisting it from a distance into a figure of 8 round the base of the horns, then he pulls down the cows, head to the left, and to the level of its foreleg, where he makes it fast, and then begins the milking operation.

---

(1) The "massaio" is the manager of the "procoio," or "masseria". He assigns the pastures, weeds out the old animals, and is entrusted with the care and rearing of the cattle belonging to the estate of which he is the agent. He has under him the cowherds ("vaccari") whose chief work is milking the cows; the "portaspese" who drive the animals to the abattoir; the "coralino" or "casaro" (cheesemaker) who directly supervises the cowherds and measures the milk and milking-time; the "appressataro" (or chief man) who takes care of the dairy cows; the barozzari (the carters), who together with the "cavalcante" (riders), manage the transport, and break in the horses required for the work of the "procoio."

These cows can be tamed and kept in the cow-shed, in which case, their milk yield increasess, sometimes amounting to 7-9 litres a day for a lactation period of 7 months.

The abattoir yield of Latium cattle is low, on account of the great development of the skeleton, the thickness of the hide, the size of the horns, etc. Nevertheless these animals fatten well and although they keep their appearance of physiological leanness, they accumulate a fair amount of fat in the abdominal cavity.

Rejected animals that are being prepared for the butcher are kept for 2 months " ad erba netta, " that is to say, in a pasture which has not been grazed before. Only in exceptional cases, when they cannot pick up sufficient in the field, are they given a little dry forage.

Only " mongane " (suckling calves) are fattened in the true sense of the word. These, in addition to sucking their dams, are allowed, to take the milk of other cows. In this way, the calves increase their weight by 900-1000 gm. a day, and are soon ready for the butcher.

537 – **Influence of Rations Restricted to the Oat Plant on Reproduction in Cattle.** — HART, E. B., STEENBOCK, H., and HUMPHREY, C. G., in *Research Bulletin* No. 49, *Agricultural Experiment Station of the University of Wisconsin*, pp. 1-22, figs 24. Madison' November, 1920.

The authors have already published data bearing on the influence of growth and reproduction of nutrients derived from maize and wheat plants (1). The present publication is a continuation of this subject with a view to studying the causes of the deficiencies in the oat ration.

The cattle used for these experiments were grade Holstein heifers, brought into the experimental herd usually at the age of 16 to 20 months and ready for breeding. These animals were kept in a well lighted basement with access to an outdoor paddock free from all vegetation. Earlier experience had shown that growth could be secured on a ration made up of 7 parts rolled oats + 7 parts oat straw. In most cases the rations were made up on the basis of equal parts of roughage to equal parts of grain or grain substitute. Sodium chloride was fed *ad libitum*.

Results showed that a ration of oats was inadequate for efficient nutrition of breeding cows. The offspring were born prematurely and were either very weak at birth or born dead. Additions of the fat soluble vitamine or casein or of both of these nutritive factors to a whole oat-straw ration calcium salts either as a carbonate (wood ashes), as a phosphate or as calcium acetate showed a distinct improvement, and offspring of fair vigour were produced. This improvement in ration was secured even without the addition of a better protein or more fat soluble vitamine to the oat grain-oat straw ration. The chief deficiency in the oat plant ration was therefore apparently calcium. Variations in the calcium content of straw will naturally occur, depending upon the soils producing them.

---

(1) See *R.*, Feb. 1918, No. 182. (*Ed.*)

The " synthetic " ration did not secure as strong offspring as the use of natural roughages such as maize stover, clover, alfalfa or marsh hay, (the latter grown on an alkaline marsh with remarkably good results).

From the data given concerning the nature and calcium content of the ration and condition of the offspring and cow, it appears that the ration of a dry breeding cow, where all other nutritive factors are satisfied, should contain at least 45 % of calcium oxide, calculated on the basis of the total ration. An air dried roughage containing 9 % of calcium oxide, provided it were fed as half of the dry matter of the ration, would probably be adequate in calcium oxide content. The authors consider it altogether possible that the calcium oxide figure advised as a minimum amount allowable in the ration of reproducing cows may be modified if the material is fresh, green plant tissue and not dried. On this point there are no data at present.

An hypothesis is given explaining the results secured, namely, that with generous sodium chloride intake and a low amount of calcium salts the surface protoplasmic films of the epithelial cells of the intestinal mucosa would present a structure in which water was the continuous phase, thus accounting for the fact that on low calcium rations there can be especially favourable conditions for continual absorption of products of intestinal origin among which may be bacterial toxins or amines.

Furthermore, attention is called to the practical significance of these studies with reference to forage and to acid soils.

538 - **Fattening Steers Without Feeding Maize Grain.** — See No. 471 of this *Review*

539 - **Fattening Native Steers for Market in Arizona, U. S.** — WILLIAMS, R. H., in *The University of Arizona College of Agriculture, Agricultural Experiment Station Bulletin*, No. 91, pp 355-396, figs 6, Tucson, Arizona, Sept. 1, 1920.

Starting on January 9, 1920, 36 steers averaging 889 lb. in weight were selected for a feeding test lasting 77 days.

Nine of these were high-grade Holsteins and the rest were mostly Holsteins sired by a Polled Shorthorn bull These cattle were divided into lots of 6 steers each

Lot I, consisting wholely of high-grade Holsteins was fed on alfalfa hay only (average daily ration per head, 28-63 lb.) and the average daily gain amounted to 1.40 lb. per head.

Lot II, average daily ration, alfalfa hay 8.99 lb. + maize silage 47.14 lb.; average daily gain, 2.39 lb.

Lot III, average daily ration, maize silage 61.76 lb. + cottonseed meal 2.66 lb.; average daily gain 1.96 lb.

Lot IV, average daily ration, alfalfa hay 4.20 lb. + maize silage 60.68 lb., + cottonseed meal 2.66 lb.; average daily gain 2.55 lb.

Lot V, average daily ration, — maize silage 52.70 lb., + cotton seed meal 2.66 lb. + ground silo maize 5.70 lb.; average daily gain 2.46 lb.

Lot VI, average daily ration, — alfalfa hay 3.97 lb. + maize silage 48.38 lb. + cottonseed meal 2.66 lb. + ground milo maize 5.77 lb.; average daily gain 2.49 lb. This lot occupies, therefore, the 2nd place as regards average daily gain, but the animals in this lot were much more uniform and fatter than those in Lot V, etc.

540 – **Comparative Values of Barley and Maize for Milch Cows.** — See No. 471 of this *Review*.

541 – **On the Extension and Improvement of Sheep-Breeding in Algeria.** — TROUETTE, G., in *La Vie Agricole et Rurale*, year X, Vol. XVIII, No. 13, pp. 200-301. Paris, March, 1921.

The author divides the Algerian flocks into the following three classes: the stationary flocks of the Tell district, the semi-migratory flocks of the high plateaux, and the far-travelling sheep of the southern region. (1)

In the Tell district (a region of vines and cereal), sheep-breeding does not occupy the prominent place that prudence would dictate, although there is no difficulty in finding shepherds, for the sons of the fellah, and the " khammes " can always be enlisted in this capacity, and modern methods can be applied with success, owing to the liberal food supplies and shelter, which are at the disposal of all the Europeans, and some of the native, stock-rearers.

On the high plateaux, the extension of colonisation has already encroached greatly upon the grazing grounds, but there are, however on these plateaux in three departments, vast tracts of uncultivated land belonging either to the State, or to native communities, where it would be possible to establish large sheep-breeding farms.

In the Southern regions, which include many tens of thousands of hectares, the existence or absence of pasturage depends upon the amount of the rainfall, and the intensity of the drought; further, the necessity of finding food for their flocks has constrained the shepherds to adopt a nomadic life and the annual migration of the sheep still persists.

In spite of these obstacles due to unfavourable environment the Algerian Administration is making every effort to change the pastoral system by increasing the watering places, this being the sole means of augmenting the number of the travelling flocks. In order to improve these continually migrating animals, the Authorities of the Southern district have founded the colonial sheep-farm of Tadmit, where selected stud animals are kept. This farm, which is situated in the valley of Oued Tadmit, 60 kilometres to the North-west of Laghouat, and only one day's march from the edge of the Sahara, has an area of 1500 hectares and together with the sheep-walks in its neighbourhood, is capable of supporting 1200 animals living under the general conditions obtaining in the South. The Administration is also directing its attention to the solution of various other problems affecting the future of the pastoral industry in Algeria.

---

(1) See *R.*, Jan. 1917. (*Ed.*)

In order to extend and improve sheep-breeding in Algeria, the author advocates that special methods should be adopted according to the conditions of the different zones where it is practised; thus,

1) *In the Tell district*, where each farm has a stationary flock, improvement must be effected both by selection and crossing.

2) *In the high Plateaux*, large flocks should be grazed on the vast tracts belonging to the State or Communities; the grazing-rights being ceded for a term of years, and in a manner hereafter to be determined, either to Societies, or individuals, having ample capital at their disposal.

3) *In the South*, water-holes must be sought for; the proper care of these would at all seasons, save many sheep dying from thirst or from infestation by parasites, and would permit of pastures hitherto useless from want of water, being turned to good account. Selection is the only means of improving the sheep.

542 - **Maize By-product for Swine.** — Robinson, W. L., in *Monthly Bulletin, Ohio Agricultural Experiment Station*, Vol. V, No. 9, pp. 247-252. Wooster, Ohio, 1920.

This is a report on two experiments in which hominy feed was compared with shelled maize for feeding hogs and four in which maize germ meal was compared with maize or used as a supplement to maize. Experiments 1, 2 and 5 were conducted in the winter the others during the summer and fall.

Use of hominy feed and maize germ meal for feeding hogs.

	Feeds offered	ration of test	ial weight er head	aily gain er head	Consumed per pound of gain ize	 ize by roduct	 Prot in supple
				lb	lb	lb	lb

	Maize, alone	15	62.4	1.14	4.45	—	—
	Maize, tankage (19 : 1)	13	59.8	1.31	4.25	—	0.17
	Maize, germ meal (3 : 1)	14	60.0	1 21	3.33	0.91	—

* Hogs on rape pasture.

It is concluded that the hominy feed used was scarcely as valuable pound for pound as maize. It is pointed out that at present manufacturers of hominy extract oil from the germs which are commonly included in the feed and that this reduction in energy value may account for the comparatively poor results from hominy feed in comparison with earlier results at the Ohio Station.

Maize germ meal alone was found to have a laxative effect. Apparently for best results it should not constitute a large percentage of the ration and when fed, should be used as a partial substitute for both the carbonaceous and the nitrogenous feed.

543 – **French Fish-Meal as a Pig-Food.** — VELU, in *La Vie Agricole et Rurale*, Year X, Vol. XVIII, No. 10, pp. 153-154. Paris, March, 1921.

As the by-product of the tinned-fish factories has not yet been used as a stock-feed in France, the author draws attention to the nutritive value of this substance, which has long been fed to all kinds of animals in Scandinavia, and the German-speaking countries; previous to the war, 40 000 tons were produced each year in England, 30 000 tons being exported to Germany. Much of it is sold under the name of "white fish meal," a standardised product containing no herrings, or similar fish.

In order to show that this fish meal should be widely used, the author carried out some experiments on two young pigs, of the same breed and age, and as far as possible, of the same weight. The animals were fed with different rations of fish meal prepared at La Rochelle and obtained by treating fresh fish in an autoclave: three hours was the time elapsing between the fish being taken from the nets and the discharge of the finished product from the apparatus. The composition of the French meal thus obtained was as follows: —

	%
Water	11.40
Proteins	60.02
Fats	9.68
Mineral substances	18.90
	100.00
Lime	7.60
Total phosphoric acid	7.03
Sodium chloride	1.52

In order to prevent errors due to individual peculiarities, the author adopted the plan of feeding the meal for periods of 40 days, separated by an interval of 10 days, during which the young pigs received ordinary rations; further, the experiments were inverted.

One of the rations contained meal, 200 gm. being given at the beginning of the experiment; the quantity was increased to 300 gm. by the end. Fish meal was substituted in equal amounts.

In the case of pig No. 1, (without fish meal), the daily increase in weight during the 40 days was 515 gm., and the cost per kg. of weight gained was 1 fr., whereas in that of the second pig (with fish meal) the daily increase in weight was 600 gm., and the cost per kg. of additional weight was 0.85 fr.

During the following 40 days, the weight of pig No. 1 (with fish meal) increased by 845 gm. daily, the cost of each additional kg. being 0.99 fr. while pig No. 2 (without fish meal) gained 574 gm. a day, the cost of each kg. gained being 1.29 fr.

With regard to mixing this highly nitrogenous food with foods poor in proteins, the author advises, especially in the case of Morocco, that it should be fed together with chopped, raw (preferably cooked) stems of the prickly pear (*Opuntia Ficus indica*).

The author also found that if fish meal is added to the rations of sucking-pigs that have been insufficiently nourished owing to the defective diet of the sow, or to the food of young pigs recovering from enteritis, the animals recover completely, regaining their former good condition and even putting on flesh rapidly. Further, the immediate arrest of the disease and the subsequent disappearance of the pathological symptoms have been observed in the case of three young pigs in the third stage of osseous cachexia.

544 - **Feeding Tests with Pigs, Using "Pig Meal" and "Pig Compo," in Australia.** — PERKINS, A. J., in *The Journal of the Department of Agriculture of South Australia* Vol. XXIV, No. 6, pp. 471-475. Adelaide, Jan., 1921.

The Metropolitan Abattoirs Board has recently placed on the market two meals prepared from its waste products and intended for the use ot pigs; they are known respectively as "Pig Meal" and "Pig Compo", and possess the following composition:

	Pig. Meal %	Pig. Compo %
Moisture	8.9	7.9
Ash	9.1	14.4
Protein	60.0	56.3
Fat	14.0	13.9
Undetermined	8.0	7.5
	100.0	100.0
Tricalcium phosphate	3.6	10.5

Definite proportions of crushed bones have been used in the preparation of "Pig Compo"; hence a decrease in the proportions of protein and fat and a corresponding increase in those of ash and phosphates.

Of the two meals, "Pig meal" has the higher feeding value; it corresponds to 85.5 starch equivalents, as against 81.1 for "Pig Compo," and the difference in value is reflected in their prices, which are respectively £. 19 and £. 18.5s per ton.

Description of Tests with Young Pigs. — Twelve young pigs were selected and divided up into 3 lots, A, B, and C. Their means were as follows: —

	lb.
Lot A	53.75
Lot B	69.00
Lot C	75.00

During the first fortnight these pigs were fed as follows (per head per day).

Lot A	2 3/4 lb. crushed barley.
Lot B	2 lb crushed barley + 1/2 lb. pig meal.
Lot C	2 lb. crushed barley + 1/2 lb. pig compo.

During the second fortnight, the barley allowance was increased all round by 3/4 lb., per head per day, and lot A was supplied with pig meal and lot B with pig compo, whilst lot C was fed with barley alone.

During the third fortnight lot A was supplied with pig compo and lot C with pig meal, whilst lot B was fed with barley alone. During this period the barley allowance was increased by 3/4 lb. in the first week, and by an additional 3/4 lb. in the second week.

The average increase in weight per head per day is given as follows:

	Barley alone	Barley and Pig meal	Barley and Pig compo
Lot A	0.42	1.76	1.36
Lot B	0.26	0.77	1.42
Lot C	1.04	1.37	0.77
Means	0.91	1.30	1.18

By substituting in the rations of young pigs, 1/2 lb. pig meal or 1/2 lb pig compo for 3/4 barley, there has been an increase in live weight of 0.39 lb., and 0.27 lb., at a cost of 1.64 d and 2.22 d per lb. live weight respectively.

545 - **Experiment on Grazing Pregnant Sows on Irrigated Meadows (Rieselgrasweiden) in Germany.** — MULLER and PRIESHOF, in the *Deutsche Landwirthschaftliche Tierzucht*, Year XXV, No. 1, pp. 7-8, Hanover, January, 1921.

The experiment in question was carried out at the Ruhlsdorf Experiment Farm for the keeping, feeding, and breeding of swine; three fertilised sows of different breeds were used. The object of the experiment was to determine whether pasture irrigated by water-channels would provide sufficient food to maintain pregnant sows of different ages without the addition of supplementary rations, and to find out how many animals an area of 0.25 hectares could support.

The pasture was 1.5 km. from the pig-sties. The pigs were taken to graze twice a day, morning and evening; they remained in the field from 2 1/2 to 3 hours, returning always at midday, and thus walking 6 kilometres every day. The experiment lasted from May 25 to September 14.

From April 14, the pigs grazed in the field twice a day and thus were well prepared for the experiment.

The grass they ate in the meadow was quite sufficient food for the sows at an advanced period of gestation ; in fact the animals gained as much as 16 kg. in weight during the course of the experiment. As a rule, no great difference was observed between the pigs of various breeds, and it thus appears that Large White Yorkshires are also good grazing animals, provided they have a head of average length, and well developed jaws.

In addition to the older sows, 5 younger ones were used in the experiment, 3 of the latter were the result of a cross between the Yorkshire and Hanover breeds, and these gained 10 kg. in weight during 16 weeks. The area of the pasture was 0.55 ha. and the number of grazing pigs varied from 9 to 20. On an average, 16.7 animals were kept on the field, so that 0.25 ha. was sufficient for 7.6 pigs. The total area was divided into 3 lots, each being grazed 4 times in succession. Each pig consumed about 15 kg. of grass a day.

Taking the market-price of a quintal of grass from the irrigated field at 7.41 fr. (1 *mark* at par = 1.2246 fr.) the cost of the pigs amounted to 1.11 fr. per day per head.

The results of the experiment shows that grass from a meadow watered by irrigation channels is an excellent and cheap food for pigs, and much more nutritive than comfrey (*Symphytum asperrimum*). As the grass yield is larger than that of comfrey, this method of feeding greatly reduces the cost of pig-rearing, especially in the case of pregnant sows and of young sows.

The authors advise pigs being fed on this forage throughout the year and suggest that the grass should be preserved by converting it into sweet silage.

546 - **Bee Keeping in the Belgian Congo.** — VANDEVELDE, in *La Meuse*, Liege, January, 22, 1919, reprinted in l'*Apiculteur* Year LXV, No. 3, pp. 72-74. Paris, March, 1921.

Information furnished to the author by E. MICHEL, Agricultural Engineer, of the Belgian Colonial Ministry.

Bees are to be found throughout the Congo ; in some regions, they are very numerous, and collect in large swarms in the hollow trunks of trees and in crevices in rocks.

The natives are very fond of honey, but they make no use of the wax. Their method of taking the honey leaves much to be desired, for they kill the bees in order to obtain it and pay no heed to keeping the swarms, but let them fly away.

In some districts, the natives make very primitive hives constructed of pliable twigs, tree bark, and plant fibres. These hives are cylindrical in shape, and about 1 m. long, their internal diameter being 30 cm. The two openings are closed by lids, one of which is perforated, so as to make a flight-hole a few centimetres in size.

When the time for collecting the honey comes, the natives open the hive at the back, and introduce smoke into it when the bees escape through the flight-hole. Then the combs are removed and ground up in order to extract the honey.

Congo wax, when well purified, is usually as good as the European product. Further, its collection, like its preparation and refining, presents no difficulties.

In 1914, the Central Administration of the Congo, had several samples of wax from the Colony examined. Some of them were of good quality one or two being even first class, and possessing the special aroma peculiar to foreign wax. The Congo product can be compared with Benguella wax, and would probably bleach well in the sun. The sample examined was valued at 340-360 fr. per 100 kg. on the wharf at Antwerp.

The Congo waxes have been investigated at the Analytical Laboratory of Louvain, and shown to possess the same physical constants as the Belgian wax.

Wax is a new article of export from the Belgian Congo, and should not be neglected. Hitherto very little of this commodity has been sent to Belgium; imports have been: — in 1905, 220 kg. valued at 165 fr.; in 1916, 3950 kg worth 15800. fr., in 1917, 15 741 kg. worth 66 899 fr.; in 1918, 2091 kg.

FARM ENGINEERING

547 - **Power Farming in Canada.** — BLACKWOOD, W. C., in *The Agricultural Gazette of Canada*, Vol. VIII, No. 1, pp. 49-50 Ottawa, Jan-Feb. 1921.

The Physics department of the Ontario Agricultural College, by correspondence with more than two hundred farmers who are using tractors, has ascertained facts relative to the comparative value of horse-power and other form of power on the Ontario farm.

The statements are not based on information received where answers to questions, differed, respecting the relative merits of horse and tractor power, or where the efficiency of the tractor for any phase of farm work was questioned 1) Most farmers agreed that horse-breeding was slightly on the decrease, but thought that other factors rather than the advent of the tractor were responsible for the decrease.

2) Tractors in large numbers have been used for so short a time that there has not been an opportunity of investigating the effect tractors will ultimately have on the number of horses on the farm.

3) The only horses that have been displaced are those kept for peak load during the spring months.

4) Total horses disposed of in 17 counties on 92 farms, from which returns were received, was 169, about 2 horses per tractor.

5) Many have not as yet disposed of their horses, as they are holding them for better prices. There will, therefore, in the near future be an increase in the number of horses displaced by the tractor owners from whom information has been received.

6) As to economy, 54 out of 92 considered their tractor a profitable investment, 32 did not know, and 6 replied in the negative. The farmer in most cases had not kept strict enough account of the cost of each horse per year to be able to give a definite answer as to the economy of the tractor relative to the horse.

7) Improved work with the tractor seems to be a significant factor.

8) So far as the replacing of " horse " power by electrical power is concerned there is as yet no available information which would lead one to believe that the influx of electrical power has had any marked effect on the horse problem on the farm.

9) Electrical systems are proving exceptionally efficient and are gaining in favour every day, according to reports received by the department.

In electrical systems we include both hydro light and power, and gas electric systems.

548 - **The Samson Tractor.** — DESSAISSAIX, R., in *Journal d'Agriculture pratique*, Year LXXXV, Vol. I, No. 13, pp. 256-257, 1 fig. Paris, April 2, 1921.

The Samson tractor, which is of American origin, is sold by the General Motors Export Co. of New York, represented in France by a Branch Office at 63 Avenue des Champs Elysées, Paris.

The motor of the Samson tractor is made at Janesville (Wisconsin), it has 4 vertical cylinders of 0.102 m. bore and 0.140 m. stroke. It can develop 20 H.P. Its two speeds are about 3 000 and 4 500 m. an hour, and its reverse is 2 000 m.

The hind driving-wheels are provided with oblique rims, they are 1.14 m. in diameter, and have tyres 0.30 m. wide. The front wheels are 0.68 m. in diameter, and their tyres are 0.10 m. in width. The chief dimensions of the machine are as follows: total length 2.75 m.; total width 1.50 m.; height 1.40 m.; weight empty 1 400 kg.

The tractor can run on either paraffin, or petrol, which is an important fact as regards the cost of fuel.

Like many other American machines, the Samson tractor can be driven and steered by the driver from his seat on the machine that is being towed. He steers by means of jointed shafts provided with indicators, the first of which telescopes into a long tube. The tractor can thus be driven with the greatest ease, especially as the driver has the work of the binder under his eyes, and by means of a rope can regulate the transmission from the motor to the driving-wheels of the tractor.

The motor of the Samson tractor has an automatic speed regulator, this is indispensable when it is used to work a belt-driven farm-machine.

549 - **An Apparatus for Making Ligatures.** — PASSELÈGUE G., in *Revue horticole*, Year 93, No. 61, pp. 283-284, 2 fig Paris, April 16, 1921.

In all operations entailing the handling of liquids, flexible tubes (of canvas or rubber) are fastened at their point of attachment by means of ligatures, which must be very firm, in order to prevent leakage. These ligatures consist either of a close spiral of wire to make which needs manual dexterity, or of attachment collars; of these latter many different types are on the market.
